Consider: Thousands of

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

Research Triangle Park, NC 27709

Patients Rescued

WELLCOVORIN[®] TABLETS =(leucovorin calcium)=

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.¹

¹Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

WELLCOVORIN® TABLETS (leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B₁₂. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g., methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below $5 \times 10^{-8} M$.^{1,2} The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e., trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.^{3,4,5}

THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

You can help us
raise the colorectal
cancer cure rate.

"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces
cancer alone.

AMERICAN CANCER SOCIETY®

BLOOD

The Journal of The American Society of Hematology

Blood: The Journal of The American Society of Hematology (ISSN 0006-4971) is published monthly, in two volumes per year, by Grune & Stratton, Inc., 6277 Sea Harbor Dr, Orlando, FL 32821. Second class postage paid at Duluth, MN, and at additional mailing offices.

POSTMASTER: Send change of address to *Blood*, c/o Grune & Stratton, Inc., PO Box 6280, Duluth, MN 55806.

Editorial correspondence should be addressed to:

John W. Adamson, MD, Editor

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

SPECIAL DEPARTMENTS

Announcements	36
Erratum	36
Information for Contributors	xvii,xvi
Advertisers' Index	xx

Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

All manuscripts submitted for consideration for publication in BLOOD should be sent to: John W. Adamson, MD, Editor, BLOOD, University District Building—Room 410, 1107 NE 45th St. Seattle, WA 98105. Telephone: (206) 545-8080.

Please note that a processing fee of \$50.00 must accompany each manuscript submitted for publication in BLOOD.

The American Society of Hematology certifies that the continuing medical education offering provided by BLOOD, *The Journal of The American Society of Hematology*, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

Radiogenic mucositis or herpes simplex?

See answer under flap. 

Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

ZOVIRAX® I.V.
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

When the problem begins with a virus,
end it with an antiviral.

Both slides are herpes simplex. You may be surprised, but especially in immunocompromised patients it is often difficult to differentiate between herpes infections and mucositis resulting from radiation therapy. Herpes simplex does not always have a classic presentation, and is easily misjudged.

Please see following page for brief summary of prescribing information.

ZOVIRAX® IV. (acyclovir sodium) STERILE POWDER / IV. INFUSION

ZOVIRAX® IV. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M² every 8 hours (750 mg/M²/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.^{1,2,3}

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.⁴

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.⁵

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.⁶

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS AND DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuring renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M²) over an hour was associated with a lower frequency—4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used

in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax (acyclovir sodium) sterile powder is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the IV fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitteriness, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 AND HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M² at a constant rate over 1 hour, every 8 hours (750 mg/M²/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M ²)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

NOW THE WAY IS CLEAR FOR YOU TO PROVIDE LEUKOPOOR PLATELETS

...WITH THE CUTTER LEUKOTRAP™ PLATELET POOLING SYSTEM.

Now, leukopoor platelets can be routinely used for treatment of patients on platelet therapy to reduce or eliminate leukocyte-associated transfusion reactions. Leukotrap is the first commercially available system for routine production of leukopoor platelets.

MOST EFFICIENT METHOD

The Leukotrap System removes 90% of leukocytes and residual red cells with only 10% platelet loss.

Leukotrap™ Pooling Bag shown after completed procedure with leukocytes and residual red cells trapped in the pouch.

SIMPLE, FAST PROCEDURE

The Leukotrap System requires minimal technician time and a standard centrifuge.

Provide a better platelet product...with the Leukotrap Platelet Pooling System.

Cutter Biological

A Division of Miles Laboratories, Inc. © 1985, Miles Laboratories, Inc.

Today's IGV. Don't settle for less.

For immunodeficiency syndromes: aggressive protection against infection

Patients without sufficient levels of antibodies face overwhelming infection, and they need help. Infusion with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens... in just minutes.

For both chronic and acute ITP in children and adults: rapid elevation of platelet levels

GAMIMUNE® N may initiate a therapeutic increase in platelets in both children and adults with idiopathic thrombocytopenic purpura (ITP).^{1*} Treatment with GAMIMUNE® N has enabled some ITP patients to undergo major surgery.¹

IGIV that's at least 98% pure gamma globulin

Cutter's fractionation method (Cohn-Oncley 6 & 9) contains all the necessary steps to produce high purity immune globulin. GAMIMUNE® N contains no foreign contaminants, no detectable levels of protein aggregates or vasoactive enzymes.² With GAMIMUNE® N you get what you expect...IGIV containing at least 98% pure gamma globulin.¹

GAMIMUNE® N
Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

Documented *in vitro* inactivation of HTLV-III virus[‡]

[‡]The Cohn-Oncley process used to produce Gamimune® N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune® N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.[‡]

"Native" IGIV

GAMIMUNE® N is manufactured without chemical modification. This means GAMIMUNE® N antibodies maintain normal opsonization capacity, have a normal distribution of IgG subgroups and provide the immunologic activity of normal plasma.[†]

Artist's interpretation of HTLV-III virus.

Today's simple, economical IGIV: the only ready-to-use liquid

Dose for dose, GAMIMUNE® N saves money by eliminating valuable reconstitution time in the pharmacy. Gram for gram of protein, GAMIMUNE® N is affordable; there is no premium price for TODAY'S IGIV.

Artist's interpretation of blood platelets.

*It is not possible to predict which patients with ITP will respond to therapy.

†In patients who respond to therapy, a rise in platelet count is generally rapid (within 1 to 5 days, transient (most often lasting from several days to several weeks) and should not be considered curative.

From the original IGIV, today's IGIV...it offers more

Please see following page for brief summary of prescribing information.

GAMIMUNE[®] N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gammune[®] N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gammune[®] N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The *in vivo* half-life of Gammune[®] N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood, there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gammune[®] N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gammune[®] N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gammune[®] N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gammune[®] N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gammune[®] N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gammune[®] N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gammune[®] N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gammune[®] N may initiate a therapeutic increase in the platelet count. In clinical studies of Gammune[®] N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gammune[®] N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gammune[®] N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gammune[®] N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gammune[®] N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gammune[®] N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PLT⁺ alloimmune antibody with platelet anti PLT⁺ specificity) also responded to treatment with Gammune[®] N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gammune[®] N should be considered, in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days) transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gammune[®] N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gammune[®] N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gammune[®] N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gammune[®] N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gammune[®] N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gammune[®] N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gammune[®] N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gammune[®] N. It is not known whether Gammune[®] N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gammune[®] N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gammune[®] N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gammune[®] N. Symptoms reported with Gammune[®] N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gammune[®] N at the infusion site was reported in some cases.

In further studies of Gammune[®] N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gammune[®] N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gammune[®] N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gammune[®] N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gammune[®] N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gammune[®] N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gammune[®] N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gammune[®] N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gammune[®] N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gammune[®] N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes, if well tolerated, the rate may be gradually increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

EXPAND YOUR CELL SURFACE STUDIES WITH TWELVE NEW PRODUCTS.

FROM A SINGLE SOURCE.

Coulter offers the broadest line of monoclonal antibodies and now provides you 12 new conjugates with a phycoerythrin derivative (RD1) or fluorescein (FITC). This chart represents a partial listing of COULTER CLONE[®] monoclonal antibodies. Coulter Immunology offers many innovative and unique products that include the first T4 subset markers, 4B4 and 2H4. The first B-cell specific antibodies. The first complete line of isotypic controls. The first and only Natural Killer cell-specific monoclonal antibodies. Coulter Immunology can provide you with total support for your cell surface phenotyping studies, giving you the most reliable, precise, and accurate answers with state-of-the-art technology.

YOUR CHOICE OF CONJUGATES FOR 2/COLOR ANALYSIS.

- Conserve volume of cell preparation by reducing sample size 50%.
- Achieve optimal color configuration for combination studies such as T4/2H4 and T4/4B4.
- Save time with dual color analysis.
- Increase flexibility and convenience when designing test protocols.
- Study activation states of Total T-cells (T11/Ta1 and T11/I3) or Immunocompetent T-cells (T3/Ta1 and T3/I3).

Blenoxane®

(sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma — Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin; larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas — Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma — Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and

dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary — This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces non-specific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes do not predict the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are non-specific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO}

falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

- (1) Maintain FiO₂ at concentrations approximately that of room air (25%) during surgery and the post-operative period.
- (2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions — In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes — These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other — Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, the Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to *BLOOD*. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: *BLOOD* will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the *BLOOD* Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared

in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in *BLOOD* represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a \$50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to: John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to *BLOOD* and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of *BLOOD* will assume that the authors of research papers published in *BLOOD* are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and two complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that when reduced they will remain at least ⅛ inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

THE
T-CELL
PUZZLE

ARE YOU MISSING THE VITAL PIECES?

Coulter Immunology can help you solve the puzzle. With the broadest line of monoclonal antibodies, Coulter Immunology provides tools to solve the puzzle of immune related disorders. We bring you vital pieces like 2H4 and 4B4, for which there are no equivalents. The inducer of help (T4+4B4+) and inducer of suppression (T4+2H4+) are functionally unique subsets of the T4 helper cells. These are available in fluorescent and phycoerythrin derivative conjugates for multiple color analysis. Ask us for references on these unique antibodies that are being used to characterize disease states, such as SLE, MS, rheumatoid arthritis, and AIDS. Return the attached card today and take advantage of our special offer. Or call us at 1-800-327-3778 (in Florida, 1-800-432-6518, Ext. 6880). Our broad line includes monoclonals for both T and B lymphocytes, monocytes, natural killer cells, specific activation markers, isotypic controls and support products. We have the pieces you're looking for today. Look for our new COULTER CLONE® monoclonal antibodies to B cell activation antigen coming soon.

COULTER IMMUNOLOGY

NOW AVAILABLE
IN STERILE POWDER FOR INJECTION

FROM ROCHE RESEARCH

Introducing a new modality in cancer therapy

Leading the way in biotherapeutics

Copyright © 1987 by Hoffmann-La Roche Inc. All rights reserved.

a breakthrough in hairy cell leukemia

- Effective in all stages of the disease.
- Statistically increased survival compared to a historical control group.
- Normalizes peripheral blood elements.
- Improves quality of life.
- Dramatically decreases the need for red blood cell and platelet transfusions.
- Virtually eliminates life-threatening opportunistic infections after several months of therapy.
- Ready-to-use injectable solution—no mixing or reconstitution.
- Also available in sterile powder for injection with diluent for reconstitution.
- SC or IM injection and fixed dosing permit administration without weight or body surface area calculation in home, office or institution.
- Caution patients not to change brands of Interferon without medical consultation, as a change in dosage may result.
- Common initial side effects, such as fever, chills, myalgia, headache and fatigue, are self-limiting and generally manageable. Myelosuppression, which can occur early in the treatment course, warrants close clinical and laboratory observation and is usually alleviated by dose reduction or temporary discontinuation of drug. Persistent fatigue is found to be less troublesome with *p.m.* or *h.s.* administration.

Injectable Solution—
3 million IU vial (3 million IU/mL) —
18 million IU vial (3 million IU/0.5 mL)

Sterile Powder for Injection—
18 million IU and 3 mL diluent for reconstitution (3 million IU/0.5 mL)

NEW

SC/IM

ROFERON[®]-A

BRAND OF
Interferon

alfa-2a, recombinant/Roche

a promise fulfilled

Before prescribing, please see complete product information on following pages.

NEW Roferon-A[®] SC/IM Interferon alfa-2a, recombinant/Roche

DESCRIPTION: Roferon-A (Interferon alfa-2a, recombinant, Roche) is a sterile protein product for use by injection. Roferon-A is manufactured by recombinant DNA technology that employs a genetically engineered *E. coli* bacterium containing DNA that codes for the human protein, Interferon alfa-2a, recombinant. Roche is a highly purified protein containing 165 amino acids, and it has an approximate molecular weight of 19,000 daltons. The purification procedure includes affinity chromatography using a murine monoclonal antibody. Fermentation is carried out in a defined nutrient medium containing the antibiotic tetracycline hydrochloride, 5 mg/liter. However, the presence of the antibiotic is not detectable in the final product. Roferon-A is supplied as an injectable solution or as a sterile powder for injection with its accompanying diluent.

Injectable Solution: The solution is colorless and contains Interferon alfa-2a, recombinant, Roche, sodium chloride, Albumin (Human) and phenol as a preservative.

Sterile Powder for Injection: The powder is white to beige and contains Interferon alfa-2a, recombinant, Roche, sodium chloride and Albumin (Human).

Diluent for Sterile Powder for Injection: The diluent contains sodium chloride, Albumin (Human) and phenol as a preservative. Each vial of Roferon-A contains 3 million or 18 million international units (IU) of Interferon alfa-2a, recombinant, Roche. The specific activity of Interferon alfa-2a, recombinant, Roche is 2×10^6 IU/mg protein. The route of administration is subcutaneous or intramuscular.

CLINICAL PHARMACOLOGY: The mechanism by which Interferon alfa-2a, recombinant, Roche, or any other interferon, exerts antitumor activity is not clearly understood. However, it is believed that direct antiproliferative action against tumor cells and modulation of the host immune response play important roles in the antitumor activity.

The biological activities of Interferon alfa-2a, recombinant, Roche are species-restricted, i.e., they are expressed in a very limited number of species other than humans. As a consequence, preclinical evaluation of Interferon alfa-2a, recombinant, Roche has involved *in vitro* experiments with human cells and some *in vivo* experiments. Using human cells in culture, Interferon alfa-2a, recombinant, Roche has been shown to have antiproliferative and immunomodulatory activities that are very similar to those of the mixture of interferon alfa subtypes produced by human leukocytes. *In vivo*, Interferon alfa-2a, recombinant, Roche has been shown to inhibit the growth of several human tumors growing in immunocompromised (nude) mice. Because of its species-restricted activity, it has not been possible to demonstrate antitumor activity in immunologically intact syngeneic tumor model systems, where effects on the host immune system would be observable. However, such antitumor activity has been repeatedly demonstrated with, for example, mouse interferon-alfa in transplantable mouse tumor systems. The clinical significance of these findings is unknown. The metabolism of Interferon alfa-2a, recombinant, Roche is consistent with that of alpha interferons in general. Alpha interferons are totally filtered through the glomeruli and undergo rapid proteolytic degradation during tubular reabsorption, rendering a negligible reappearance of intact alpha interferon in the systemic circulation. Small amounts of radiolabeled Interferon alfa-2a, recombinant, Roche appear in the urine of isolated rat kidneys, suggesting near complete reabsorption of Interferon alfa-2a, recombinant, Roche catabolites. Liver metabolism and subsequent biliary excretion are considered minor pathways of elimination for alpha interferons.

The serum concentrations of Interferon alfa-2a, recombinant, Roche reflected a large intersubject variation in both healthy volunteers and patients with disseminated cancer.

In healthy people, Interferon alfa-2a, recombinant, Roche exhibited an elimination half-life of 3.7 ± 8.5 hours (mean 5.1 hours), volume of distribution at steady state of 0.223 ± 0.748 L/kg (mean 0.400 L/kg) and a total body clearance of 2.14 to 3.62 mL/min/kg (mean 2.79 mL/min/kg) after a 36 million IU (2.2×10^6 pg) intravenous infusion. After intramuscular and subcutaneous administrations of 36 million IU, peak serum concentrations ranged from 1500 to 2580 pg/mL (mean 2020 pg/mL) at a mean time to peak of 3.8 hours and from 1250 to 2320 pg/mL (mean 1730 pg/mL) at a mean time to peak of 7.3 hours, respectively. The apparent fraction of the dose absorbed after intramuscular injection was greater than 80% .

The pharmacokinetics of Interferon alfa-2a, recombinant, Roche after single intramuscular doses to patients with disseminated cancer were similar to those found in healthy volunteers. Dose proportional increases in serum concentrations were observed after single doses up to 198 million IU. There were no changes in the distribution or elimination of Interferon alfa-2a, recombinant, Roche during twice daily (0 to 36 million IU), once daily (1 to 54 million IU), or three times weekly (1 to 135 million IU) dosing regimens up to 28 days of dosing. Multiple intramuscular doses of Interferon alfa-2a, recombinant, Roche resulted in an accumulation of 2 to 4 times the single dose serum concentrations. Pharmacokinetic information in patients with hairy cell leukemia is presently unknown.

The acute parenteral toxicity of Interferon alfa-2a, recombinant, Roche has been studied in mice, rats, rabbits and ferrets at doses up to 30 million IU/kg intravenously, and 500 million IU/kg intramuscularly. No treatment-related mortality was noted in any species given Interferon alfa-2a, recombinant, Roche by any of the routes of administration.

Effects on Hairy Cell Leukemia: During the first one to two months of treatment of patients with hairy cell leukemia, significant depression of hematopoiesis was likely to occur. Subsequently, there was improvement in circulating blood cell counts.

Of the 75 patients who were evaluable for efficacy following at least 16 weeks of therapy, 46 (61%) achieved complete or partial response. Twenty-one patients (28%) had a minor remission, eight (11%) remained stable, and none had worsening of disease. All patients who achieved either a complete or partial response had complete or partial normalization of all peripheral blood elements including hemoglobin level, white blood cell, neutrophil, monocyte and platelet counts with a concomitant decrease in peripheral blood and bone marrow hairy cells. Responding patients also exhibited a marked reduction in red blood cell and platelet transfusion requirements, a decrease in infectious episodes and improvement in performance status. The probability of survival for two years in patients receiving Roferon-A (94%) was statistically increased compared to a historical control group (75%).

ROFERON-A (Interferon alfa-2a, recombinant/Roche)

INDICATIONS AND USAGE: Roferon-A is indicated for use in the treatment of hairy cell leukemia in people 18 years of age or older. Studies have shown that Roferon-A can produce clinically meaningful regression or stabilization of this disease, both in previously splenectomized and nonsplenectomized patients.^{2,3} Prior to initiation of therapy, tests should be performed to quantitate peripheral blood hemoglobin, platelets, granulocytes and hairy cells and bone marrow hairy cells. These parameters should be monitored periodically (e.g., monthly) during treatment to determine whether response to treatment has occurred. If a patient does not respond within six months, treatment should be discontinued. If a response to treatment does occur, treatment should be continued until no further improvement is observed and these laboratory parameters have been stable for about three months. It is not known whether continued treatment after that time is beneficial. Studies are in progress to evaluate this question.

CONTRAINDICATIONS: Roferon-A is contraindicated in patients with known hypersensitivity to alpha interferon, mouse immunoglobulin or any component of the product.

WARNINGS: Roferon-A should be administered under the guidance of a qualified physician. (See DOSAGE AND ADMINISTRATION.) Appropriate management of the therapy and its complications is possible only when adequate diagnostic and treatment facilities are readily available.

Roferon-A should be used with caution in patients with severe preexisting cardiac disease, severe renal or hepatic disease, seizure disorders and/or compromised central nervous system function.

Because of the possibility of severe or even fatal adverse reactions, patients should be informed not only of the benefits of therapy but also of the risks involved.

Roferon-A should be administered with caution to patients with cardiac disease or with any history of cardiac illness. No direct cardiotoxic effect has been demonstrated, but it is likely that acute, self-limited toxicities (i.e., fever, chills) frequently associated with Roferon-A administration may exacerbate preexisting cardiac conditions. Rarely, myocardial infarction has occurred in patients receiving Roferon-A.

Caution should be exercised when administering Roferon-A to patients with myelosuppression.

Central nervous system adverse reactions have been reported in a number of patients. These reactions included decreased mental status, exaggerated central nervous system function, and dizziness. More severe obtundation and coma have been rarely observed. Most of these abnormalities were mild and reversible within a few days to three weeks upon dose reduction or discontinuation of Roferon-A therapy. Careful periodic neuropsychiatric monitoring of all patients is recommended.

Leukopenia and elevation of hepatic enzymes occurred frequently but were rarely dose-limiting. Thrombocytopenia occurred less frequently. Proteinuria and increased cells in urinary sediment were also seen infrequently. Rarely, significant hepatic, renal and myelosuppressive toxicities were noted.

PRECAUTIONS: *General:* In all instances where the use of Roferon-A is considered for chemotherapy, the physician must evaluate the need and usefulness of the drug against the risk of adverse reactions. Most adverse reactions are reversible if detected early. If severe reactions occur, the drug should be reduced in dosage or discontinued and appropriate corrective measures should be taken according to the clinical judgment of the physician. Reinstitution of Roferon-A therapy should be carried out with caution and with adequate consideration of the further need for the drug and alertness as to possible recurrence of toxicity. The minimum effective dose of Roferon-A for treatment of hairy cell leukemia has not been established.

Information for Patient: Patients should be cautioned not to change brands of interferon without medical consultation, as a change in dosage may result. Patients should be informed regarding the potential benefits and risks attendant to the use of Roferon-A. If home use is determined to be desirable by the physician, instructions on appropriate use should be given, including review of the contents of the enclosed Patient Information Sheet. Patients should be well hydrated, especially during the initial stages of treatment.

Laboratory Tests: Periodic complete blood counts and liver function tests should be performed during the course of Roferon-A treatment. They should be performed prior to therapy and at appropriate periods during therapy. Since responses of hairy cell leukemia are not generally observed for one to three months after initiation of treatment, very careful monitoring for severe depression of blood cell counts is warranted during the initial phase of treatment. Those patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer should have electrocardiograms taken prior to and during the course of treatment.

Carcinogenesis, Mutagenesis and Impairment of Fertility:

Carcinogenesis: Roferon-A has not been tested for its carcinogenic potential. *Mutagenesis:* A. Internal studies—Ames tests using six different tester strains, with and without metabolic activation, were performed with Roferon-A up to a concentration of 1920 µg/plate. There was no evidence of mutagenicity. Human lymphocyte cultures were treated *in vitro* with Roferon-A at noncytotoxic concentrations. No increase in the incidence of chromosomal damage was noted. B. Published studies—There are no published studies on the mutagenic potential of Roferon-A. However, a number of studies on the genotoxicity of human leukocyte interferon have been reported.

A chromosomal defect following the addition of human leukocyte interferon to lymphocyte cultures from a patient suffering from a lymphoproliferative disorder has been reported.

In contrast, other studies have failed to detect chromosomal abnormalities following treatment of lymphocyte cultures from healthy volunteers with human leukocyte interferon.

It has also been shown that human leukocyte interferon protects primary chick embryo fibroblasts from chromosomal aberrations produced by gamma rays. *Impairment of Fertility:* Roferon-A has been studied for its effect on fertility in Macaca mulatta (rhesus monkeys). Nonpregnant rhesus females treated with Roferon-A at doses of 5 and 25 million IU/kg day have shown menstrual cycle irregularities, including prolonged or shortened menstrual periods and erratic bleeding; these cycles were considered to be anovulatory on the basis that reduced progesterone levels were noted and that expected increases in preovulatory estrogen and luteinizing hormones were not observed. These monkeys returned to a normal menstrual rhythm following discontinuation of treatment. *Drug Interactions:* Interactions between Roferon-A and other drugs have not been fully evaluated.

PREGNANCY: Teratogenic Effects: Pregnancy Category C. Roferon-A has been shown to demonstrate a statistically significant increase in abortifacient activity in rhesus monkeys when given at approximately 20 to 500 times the human dose. A study in pregnant rhesus monkeys treated with 1, 5 or 25 million IU/kg day of Roferon-A in their early to midfetal period (days 22 to 70 of gestation) has failed to demonstrate teratogenic activity for Roferon-A. There are no adequate and well-controlled studies in pregnant women. *Nonteratogenic Effects:* Dose-related abortifacient activity was observed in pregnant rhesus monkeys treated with 1, 5 or 25 million IU/kg day of Roferon-A.

ROFERON[®]-A (Interferon alfa-2a, recombinant Roche)

in their early to mid fetal period (days 22 to 70 of gestation). A late-fetal period (days 79 to 100 of gestation) is in progress and as yet there have been no reports of any increase in rate of abortion.

Usage in Pregnancy. Safe use in human pregnancy has not been established. Therefore, Roferon-A should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. Information from primate studies showed dose-related menstrual irregularities and an increased incidence of spontaneous abortions. Increases in serum estradiol and progesterone concentrations have been reported in women treated with human leukocyte interferon- α . Therefore, fertile women should not receive Roferon-A unless they are using effective contraception during the therapy period.

Male fertility and teratogenic evaluations have yielded no significant adverse effects to date.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from Roferon-A, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use. Safety and effectiveness in children under 18 years of age have not been established.

ADVERSE REACTIONS. The following data on adverse reactions are based on the subcutaneous or intramuscular administration of Roferon-A as a single agent for the treatment of 53 patients with hairy cell leukemia during investigational trials in the United States.

Flu-like syndromes consisting of fatigue (89%), fever (98%), chills (64%), myalgias (73%) and headache (71%) occurred in the majority of patients and tended to diminish with continuing therapy. Other side effects such as anorexia (46%), nausea (32%), emesis (2%), diarrhea (29%), dizziness (21%), rash (18%), change in taste (13%), sinusitis or inflammation of the oropharynx (16%), dry skin or pruritus (13%), weight loss (14%) were observed with moderate frequency. Less commonly, dyspareunia (8%), paresthesias (6%), numbness (6%), partial alopecia (5%), reactivation of herpes labialis (8%), transient impotence (6%) and arthralgia (5%) were also observed. Rarely (< 3%), central nervous system effects including decreased mental status, depression, visual disturbances, sleep disturbances and nervousness, as well as cardiac adverse events, including hypertension, chest pain, arrhythmias and palpitations, were reported. Adverse experiences which occurred rarely and may have been related to underlying disease included epistaxis, bleeding gums, ecchymosis and petechiae. Miscellaneous adverse events, such as night sweats, urticaria, conjunctivitis and inflammation at the site of injection, were also rarely observed. Roferon-A has a safety profile similar to that of the treatment of many other types of cancer under investigational trials in the United States. These studies generally utilized higher doses (10 to 50 million IU/m²). All of the previously described adverse reactions which occurred in patients with hairy cell leukemia were also observed in patients receiving higher doses. The incidence of most adverse reactions was similar between the two groups, but tended to be more severe in patients who received higher doses of Roferon-A. Some additional adverse effects which occurred in these patients included confusion (10%), hypotension (6%), lethargy (3%) and edema (3%). Adverse experiences occurring in less than 1% of these patients and observed only in patients with malignancies other than hairy cell leukemia are as follows: **Gastrointestinal**—abdominal fullness, hypermotility and heartburn; **Central Nervous System**—gait disturbance, poor coordination, hallucinations, syncope, seizures, encephalopathy, psychomotor retardation, coma, stroke, transient ischemic attacks, aphasia, aphonia, dysarthria, dyspraxia, forgetfulness, amnesia, sedation, apathy, anxiety, emotional lability, irritability, hyperactivity, involuntary movements, claustrophobia and loss of libido; **Peripheral Nervous System**—muscle contractions; **Cardiovascular**—congestive heart failure, pulmonary edema, myocardial infarction, Raynaud's phenomenon and hot flashes; **Pulmonary**—bronchospasm and tachypnea; **Miscellaneous**—excessive salivation and flushing of skin. **Abnormal Laboratory Test Values.** The percentage of patients with hairy cell leukemia or with other types of malignancies who experienced a significant abnormal laboratory test value at least once during their treatment is shown in the following table.

ABNORMAL LABORATORY TEST VALUES

	Hairy Cell Leukemia (n = 63)	Overall Safety Summary* (n = 1019)
Hematologic		
Leukopenia	59%	69%
Neutropenia	39%	58%
Thrombocytopenia	42%	42%
Decreased Hemoglobin	36%	6.3%
Decreased Hematocrit	43%	12.5%
Mean Time to Nadir		
WBC	38 days	22 days
Platelets	19 days	17 days
Hepatic		
SGOT	47%	78%
Alkaline Phosphatase	18%	48%
LDH	12%	47%
Bilirubin	1.6%	31%
Renal/Urinary		
BUN	2%	10%
Serum Creatinine	3%	10%
Uric Acid†	6%	15%
Proteinuria‡	10%	25%
Other Chemistry Tests		
Hypocalcemia	10%	51%
Elevated Serum Glucose§	33%	39%
Elevated Serum Phosphorus	2%	17%

*Patients with hairy cell leukemia are included in this overall summary.

†The majority of abnormal uric acid values and proteinuria were of minimal severity. Since these abnormalities are commonly observed in patients with advanced malignancy, it is difficult to ascertain their relationship to Roferon-A treatment.

‡Random glucose determination.

§Neutralizing antibodies to Roferon-A were detected in approximately 27% of all patients (3.4% for patients with hairy cell leukemia). No clinical sequelae of their presence have been documented thus far. Antibodies to human leukocyte interferon may occur spontaneously in certain clinical conditions (cancer, systemic

ROFERON[®]-A (Interferon alfa-2a, recombinant Roche)

lupus erythematosus, herpes zoster) in patients who have never received exogenous interferon.

DOSAGE AND ADMINISTRATION: Hairy Cell Leukemia—The induction dose of Roferon-A is 3 million IU daily for 16 to 24 weeks, administered as a subcutaneous or intramuscular injection. Subcutaneous administration is particularly advisable for, but not limited to, thrombocytopenic patients (platelet count < 50,000) or for patients at risk for bleeding. The recommended maintenance dose is 3 million IU, three times per week. Dosage reduction by one-half or withholding of individual doses may be needed when severe adverse reactions occur. The use of doses higher than 3 million IU is not recommended. Patients should be treated for approximately six months before the physician determines whether to continue therapy in patients who respond or discontinue therapy in patients who did not respond. Patients with hairy cell leukemia have been treated for up to 20 consecutive months. The optimal duration of treatment for this disease has not been determined.

If severe reactions occur, dosage should be modified (50% reduction) or therapy should be temporarily discontinued until the adverse reactions abate. The need for dosage reduction should take into account the effects of prior X-ray therapy or chemotherapy that may have compromised bone marrow reserve. The minimum effective dose of Roferon-A has not been established.

The subcutaneous or intramuscular routes of administration should be used. Subcutaneous administration is particularly suggested for, but not limited to, patients who are thrombocytopenic (platelet count < 50,000) or who are at risk for bleeding.

Injectable Solution:

3 million IU Roferon-A per vial—Each 1 mL contains 3 million IU of Interferon alfa-2a, recombinant Roche, 9 mg sodium chloride, 5 mg Albumin (Human) and 3 mg phenol as a preservative.

18 million IU Roferon-A per vial—Each 1 mL contains 6 million IU of Interferon alfa-2a, recombinant Roche, 9 mg sodium chloride, 5 mg Albumin (Human) and 3 mg phenol as a preservative. Each 0.5 mL contains 3 million IU of Interferon alfa-2a, recombinant Roche.

Sterile Powder for Injection:

18 million IU Roferon-A per vial—Reconstitute with 3 mL diluent and swirl gently to dissolve. When reconstituted with Diluent for Roferon-A, each 1 mL of reconstituted solution contains 6 million IU Interferon alfa-2a, recombinant Roche, 9 mg sodium chloride, 5 mg Albumin (Human) and 3 mg phenol as a preservative. Each 0.5 mL contains 3 million IU of Interferon alfa-2a, recombinant Roche. Once the powder is reconstituted, it must be used within thirty (30) days.

The sterile powder and its accompanying diluent, the reconstituted solution and the injectable solution should be stored in the refrigerator at 36° to 45° F (2° to 8° C). Do not freeze or shake.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

HOW SUPPLIED:

Roferon-A Injectable Solution: Vials containing 3 million IU Interferon alfa-2a, recombinant Roche (3 million IU/mL). Boxes of 10 (NDC 0004-1987-01).

Roferon-A Injectable Solution: Vials containing 18 million IU Interferon alfa-2a, recombinant Roche (3 million IU/0.5 mL). Boxes of 1 (NDC 0004-1988-09).

Roferon-A Sterile Powder for Injection: Vials containing 18 million IU Interferon alfa-2a, recombinant Roche, with accompanying diluent. Boxes of 1 (NDC 0004-1993-09).

Coagulation Factor Deficient Human Plasma

- Substrate Quality
- Stable
- Fresh Frozen
- Mono-Specific

COAGULATION DEFICIENCIES AVAILABLE:

Factor I (Afibrinogenemia)	Factor IX	VonWillebrand Trait
Factor II	Factor X	(Mild and Severe)
Factor V	Factor XI	Prekallikrein
Factor VII	Factor XII	Kininogen (HMW)
Factor VIII	Factor XIII	Passovoy Trait
Factor VIII Inhibitor		Protein C

HEMATOLOGY PRODUCTS AVAILABLE:

Pooled Normal Plasma
Assayed Normal Plasma
Platelet Free Plasma

Aged Serum
Adsorbed Plasma
Coumadinized Plasma

- Plasmas are fresh frozen, citrated plasmas drawn from carefully screened HUMAN donors with congenital coagulation factor deficiencies.
- Shipments are packed in dry ice and usually delivered within 24 hours.
- Special arrangements are made to ship plasma in required volumes in vials (0.5 to 5.0 ml), in bags or on standing orders.

The first troche treatment for oropharyngeal candidiasis.

Before treatment.¹

After treatment with MYCELEX Troche.¹

High clinical cure* rates.

A clinical cure rate of 96% was achieved in one randomized double-blind trial² in which MYCELEX Troche was administered to patients with oropharyngeal candidiasis. Other investigators have concluded that MYCELEX Troche "is highly effective treatment for chronic oral candidiasis."³

Dramatic improvement in symptoms.

Patients attain a high degree of relief at the end of therapy, as evidenced by the dramatic decrease in severity of glossitis, patches, perleche, pain, and other clinical signs and symptoms of thrush.⁴

Good patient acceptance, minimal side effects.

With MYCELEX Troche, messy suspensions and lengthy swishing are things of the past. MYCELEX Troche has a pleasant, slightly sweet taste. And an entire day's therapy—5 troches—can easily be carried in pocket or purse.

Based on a study of 52 episodes of oropharyngeal candidiasis, the investigators stated: "We believe that the troche form of clotrimazole...in the treatment of thrush in any patient population...is both effective and safe."^{2†}

*Clinical cure is defined as absence of signs and symptoms of the disease.

†See adjacent page for summary of prescribing information, including contraindications and adverse reactions.

Mycelex[®] Troche

(clotrimazole) 10 mg

The only troche for oropharyngeal candidiasis.

MYCELEX® (clotrimazole) TROCHE

Indications and Usage: Mycelex Troches are indicated for the local treatment of oropharyngeal candidiasis. The diagnosis should be confirmed by a KOH smear and/or culture prior to treatment.

Contraindications: Mycelex Troches are contraindicated in patients who are hypersensitive to any of the components.

Warning: Mycelex Troches are not indicated for the treatment of systemic mycoses.

Precautions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials. In most cases the elevations were minimal and it was often impossible to distinguish effects of clotrimazole from those of other therapy and the underlying disease (malignancy in most cases). Periodic assessment of hepatic function is advisable particularly in patients with preexisting hepatic impairment.

Since patients must be instructed to allow each troche to dissolve slowly in the mouth in order to achieve maximum effect of the medication, they must be of such an age and physical and/or mental condition to comprehend such instructions.

Carcinogenesis: An 18-month dosing study with clotrimazole in rats has not revealed any carcinogenic effect.

Usage in Pregnancy: Pregnancy Category C. Clotrimazole has been shown to be embryotoxic in rats and mice when given in doses 100 times the adult human dose (in mg/kg), possibly secondary to maternal toxicity. The drug was not teratogenic in mice, rabbits, and rats when given in doses up to 200, 180, and 100 times the human dose.

Clotrimazole given orally to mice from nine weeks before mating through weaning at a dose 120 times the human dose was associated with impairment of mating, decreased number of viable young, and decreased survival to weaning. No effects were observed at 60 times the human dose. When the drug was given to rats during a similar time period at 50 times the human dose, there was a slight decrease in the number of pups per litter and decreased pup viability.

There are no adequate and well-controlled studies in pregnant women. Clotrimazole troches should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Pediatric Use: Safety and effectiveness of clotrimazole in children below the age of three years have not been established; therefore, its use in such patients is not recommended.

Adverse Reactions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials (see Precautions section).

Nausea and vomiting was reported in about one in 20 patients.

Dosage and Administration: Mycelex Troches are administered only as a lozenge that must be dissolved slowly in the mouth. The recommended dose is one troche five times a day for 14 consecutive days. Only limited data are available on the safety and effectiveness of the clotrimazole troche after prolonged administration; therefore, therapy should be limited to short-term use, if possible.

How Supplied: Mycelex Troches—white, discoid, uncoated tablets are supplied in bottles of 70 and 140. Each tablet will be identified with the following: Miles 095.

Store below 36°F (30°C), avoid freezing.

HELENA HAS THE ANSWERS

BRIEF REVIEW

Subunit Assembly of Hemoglobin: An Important Determinant of Hematologic Phenotype

By H. Franklin Bunn

Hemoglobin's physiologic properties depend on the orderly assembly of its subunits in erythropoietic cells. The biosynthesis of α - and β -globin polypeptide chains is normally balanced. Heme rapidly binds to the globin subunit, either during translation or shortly thereafter. The formation of the $\alpha\beta$ -dimer is facilitated by electrostatic attraction of a positively charged α -subunit to a negatively charged β -subunit. The $\alpha\beta$ -dimer dissociates extremely slowly. The difference between the rate of dissociation of $\alpha\beta$ - and $\alpha\gamma$ -dimers with increasing pH explains the well-known alkaline resistance of Hb F. Two dimers combine to form the functional $\alpha_2\beta_2$ -tetramer. This model of hemoglobin assembly explains the different levels of positively charged and negatively charged mutant hemoglobins that are encountered in heterozygotes and the effect of α -thalassaemia and heme deficiency states in modifying the level of the

variant hemoglobin as well as Hb A₂. Electrostatic interactions also affect the binding of hemoglobin to the cytoplasmic surface of the red cell membrane and may underlie the formation of target cells. Enhanced binding of positively charged variants such as S and C trigger a normally dormant pathway for potassium and water loss. Thus, the positive charge on β^c is responsible for the two major contributors to the pathogenesis of Hb SC disease: increased proportion of Hb S and increased intracellular hemoglobin concentration. It is likely that electrostatic interactions play an important role in the assembly of a number of other multisubunit macromolecules, including membrane receptors, cytoskeletal proteins, and DNA binding proteins.

© 1987 by Grune & Stratton, Inc.

JUST as the accuracy and durability of a fine watch depend on the well-engineered fit of its moving parts, many regulatory events in biology require dynamic interaction between the "moving parts" of multisubunit proteins. Hemoglobin is probably the most thoroughly studied example; its physiologic function depends on gear- and ratchet-like movement between its subunits.¹⁻³ Our understanding of how hemoglobin works at the molecular and atomic levels is based on contributions from many disciplines, including structural and physical biochemistry, molecular genetics, and clinical medicine. Lessons learned from hemoglobin can be applied with profit to a number of other multisubunit proteins, some of which are of special interest to hematologists.

A rigorous set of constraints is involved in the orderly construction of a multisubunit protein. In most instances, including hemoglobin, the unlike subunits are products of different genes. (Exceptions include insulin and haptoglobin, whose subunits are cleaved from a precursor polypeptide and linked by disulfide bonds.) Efficient biosynthesis of hemoglobin requires balanced production of α and β polypeptide chains. Moreover, enough heme must be synthesized in the mitochondria to provide each of the newly made globin chains with its all-important prosthetic group. The reaction between heme and apoglobin is rapid.^{4,5} Therefore, it is likely that heme is inserted into its proper niche either during translation of the nascent globin chain or shortly thereafter. A slight mismatch in globin chain biosynthesis can be tolerated because erythroid precursor cells have an efficient

adenosine triphosphate-dependent proteolytic system⁶⁻⁸ that attacks free subunits^{9,10} but leaves assembled dimers and tetramers unscathed. Likewise, excess heme can be catabolized by an inducible microsomal oxygenase.¹¹ Despite intensive experimental scrutiny, the mechanisms responsible for the precise coordination between the synthesis of globin subunits and that of heme are unclear. These good housekeeping practices are essential to normal red cell viability. The thalassemias are prototypes of chain imbalance. Most of the phenotypic features of both the β -thalassemias and the α -thalassemias can be explained by either the deleterious effect of free subunits on the red cell membrane or the accumulation of these relatively insoluble and noncooperative subunits in the cytosol.

SUBUNIT ASSEMBLY OF HEMOGLOBIN

Once equivalent amounts of α - and β -subunits have been translated on their respective polyribosomes, and once heme has been inserted, the hemoglobin subunits are now faced

with the challenging task of diffusing within the thick tomato soup and finding unlike partner subunits so that they can assemble into the functional $\alpha_2\beta_2$ -tetramer. A growing body of hematologic and experimental evidence indicates that subtle alterations in the rate of subunit assembly are prime determinants of the distribution of hemoglobins seen in normal and pathologic red cells and can explain a number of hitherto puzzling phenotypic features.

The steps in hemoglobin assembly are depicted schematically in Fig 1. Note that a heme-intact β -subunit will combine with a heme-intact α -subunit or, alternatively, may aggregate with like β -subunits to form β_4 -tetramers or Hb H. Under normal circumstances the concentration of free β -subunits is likely to be sufficiently low that there is no significant amount of β_4 in the cytosol of erythropoietic cells. In contrast, in certain types of α -thalassemia, Hb H and its fetal counterpart Hb Barts (γ_4) can be detected, and in the case of hydrops fetalis (deletion of all four α -globin genes [---/---]), these homotetramers are virtually the only hemoglobins detected.

The critical and rate-limiting step in hemoglobin assembly is the simple bimolecular reaction $\alpha + \beta \rightarrow \alpha\beta$. This noncovalent reaction is nearly irreversible. As discussed later, the reverse reaction does occur but slowly. In contrast, the combination of two like $\alpha\beta$ -dimers to form the $\alpha_2\beta_2$ -tetramer is readily reversible.^{12,13} The interface at which these two dimers slide on each other is crucial to the cooperative behavior of hemoglobin.¹⁻³

Fig 1. Assembly of hemoglobin. The α - and β -globin polypeptides are translated on their respective mRNAs. On binding of heme, the protein folds into its native three-dimensional structure. The binding of α - and β -hemoglobin subunits to each other is facilitated by electrostatic attraction. An unstable intermediate encounter complex can rearrange to form the stable $\alpha\beta$ -dimer. Two dimers combine to form the functional $\alpha_2\beta_2$ -tetramer.

SURVEY OF MUTANT HEMOGLOBINS

The vast body of information on the human hemoglobin variants can provide special insights into the mechanism of subunit assembly. Several independent factors influence the formation of normal and mutant hemoglobins.^{3,14} A few variant subunits are synthesized at a significantly lower rate than that of their normal counterparts. Examples include Hb E¹⁵⁻¹⁷ and Hb Knossos,¹⁸ in which the mutations lead to defective β -globin mRNA processing, and therefore significantly reduced protein synthesis and a thalassemic phenotype. In contrast, the vast majority of variant subunits appear to have normal rates of transcription and translation. Another factor that influences the amount of variant hemoglobin in the red cell is the stability of the variant subunit. Among the 70-odd unstable β -globin variants that have been reported to date, most constitute less than 30% of the total hemoglobin, owing to increased catabolism of the variant both in erythroid precursor cells and in the circulation.^{3,19}

A third factor, differences in the rates of subunit assembly, could explain the variability in the levels of most of the stable hemoglobin variants. Even small differences in the rates of combination of variant subunits with normal partner subunits could have a significant effect on the distribution of hemoglobins in the red cell. In order to explore this hypothesis, we surveyed reports in the literature on β -globin variants.²⁰ Humans inherit two β -globin genes, one from each parent. Accordingly, if a variant β -subunit is translated at a normal rate and has normal stability and solubility, red cells of heterozygotes would be expected to contain equal amounts of the normal and variant hemoglobin.* However, the reported values show unexpected variability. Many of the commonly encountered β -globin variants are present in significantly lower amounts than in Hb A. As shown in Fig 2, these variants tend to be positively charged. In the presence of α -thalassemia, where there is a limiting amount of α -chains, the proportion of the positively charged variant is further decreased in proportion to the number of α -globin genes deleted. In contrast, negatively charged variants are often present in heterozygote red cells in amounts greater than Hb A. In one case (Hb J-Baltimore), the presence of α -thalassemia resulted in an increase in the proportion of the variant. Another variant (Hb N-Baltimore) was unchanged by the presence of α -thalassemia.

The levels of the stable β -globin variants shown in Fig 2 are independent of the location of the amino acid substitution on the surface of the molecule. All substitutions at the interfaces between α and β subunits were excluded from this analysis because structural alterations at these sites could have a direct effect on hemoglobin assembly independent of charge. Moreover, α -globin variants were excluded for two reasons. First, the levels of α -globin mutants are markedly affected by α -thalassemia, a condition that is often not well

*In normal red cells, the minor components, Hb A₂, F, and the glycosylated hemoglobins (Hb A_{1c}, A_{1b}, etc) compose about 10% of the total hemoglobin. Therefore, in β -globin heterozygotes the variant and normal Hb A would each constitute 45% of the total if they had equal rates of synthesis and assembly as well as equal stability.

Fig 2. (A) Effect of charge on the proportion of abnormal hemoglobin in individuals heterozygous for 72 stable β -globin variants. Each data point represents a mean value for a given variant. The solid points (●) denote measurements of Huisman^{20a} using high-resolution chromatography. Substitutions involving a histidine residue were scored as a change of one half charge. The "-1" group differs significantly from the "+1" group ($P < .001$) and from the "0" group ($P < .05$). (B) Effect of α -thalassemia on the proportion of six positively charged β -chain variants (●) and two negatively charged variants (○) (data from Bunn and McDonald²⁰).

documented in the literature. Secondly, there is a twofold difference in the expression of the two tandem α -globin genes both at the mRNA level^{21,22} and at the protein level.²³ Both of these factors would confound interpretation of levels of α -globin mutants in heterozygotes.

These hematologic observations suggest that the surface charge of subunits is an important determinant of hemoglobin assembly. This hypothesis can be tested by preparing normal and variant subunits, mixing them, and monitoring the formation and dissociation of $\alpha\beta$ -dimers.

DISSOCIATION OF $\alpha\beta$ -DIMER INTO MONOMERS

Until recently the combination of α - and β -monomers to form the $\alpha\beta$ -dimer was generally regarded as an irreversible reaction. Extreme, nonphysiologic solvent conditions were thought to be necessary to split the dimer into its constituent subunits. However, experiments measuring the displacement of α -subunits with radio-labeled α -subunits have shown conclusively that under physiologic conditions, the $\alpha\beta$ -dimer slowly dissociates into monomers.^{24,25} This first-order reaction is sensitive to temperature, pH, and ionic strength. Measurement of dimer dissociation has provided an explanation of a long-recognized and useful property of fetal hemoglobin: resistance to alkaline denaturation.²⁵ The $\alpha\gamma$ -dimer of Hb F dissociates about half as rapidly as that of Hb A at neutral pH. As pH is increased, the difference widens. The relatively slow rate of $\alpha\gamma$ dissociation at high pH compared

to that of $\alpha\beta$ dimer can be explained by the substitution of threonine for cysteine at position 112. This residue is one of the three sites at the intersubunit interface at which the γ - and β -subunits differ. It is likely that ionization of the sulfhydryl group of β 112 Cys at high pH contributes to subunit dissociation and subsequent denaturation of Hb A.²⁶

ASSOCIATION OF MONOMERS INTO $\alpha\beta$ -DIMERS

The rate-limiting step in hemoglobin assembly is the combination of heme-intact α - and β -globin subunits to form the $\alpha\beta$ -dimer. This reaction can be monitored by spectroscopic means to give a second-order rate constant of about $8 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$.^{27,28} This rate is nearly three orders of magnitude slower than the diffusion-limited rate for the combination of two macromolecules the size of globin subunits. Because of inherent inaccuracies in these spectroscopic measurements, we used subunit competition experiments to examine the assembly of hemoglobin variants and to test the effect of surface charge.²⁹ Previous experiments had shown that α -subunits combine about two times more readily with β^A than with β^S .³⁰⁻³³

Our subunit competition experiments were performed by incubating varying amounts of α -subunits with an equimolar amount of normal (β^A) and variant (β^X) β -subunits and then measuring the amounts of hemoglobin formed (Hb A and Hb X) by high-performance liquid chromatography and isoelectric focusing. Globin subunits were prepared with sufficient care that the addition of α -chains to an equivalent amount of β -chains resulted in the stoichiometric formation of hemoglobin tetramers having completely normal oxygen binding. These competition experiments closely simulate the *in vivo* situation in erythroblasts of heterozygotes where normal and variant β -subunits are competing for α -subunits. A low ratio of α to $\beta^A + \beta^X$ mimics the coexistence of α -thalassemia. At physiologic pH (7.2), the α -subunit has 2.4 positive charges, while the β^A subunit has 2.5 negative charges. Therefore, it makes sense that the two subunits would be pulled together by electrostatic attraction. This attraction would be altered if a variant β -subunit (β^X) differed significantly in surface charge from β^A . As shown in Fig 3, in the presence of limiting amounts of α -chains, the formation of Hb X relative to Hb A was directly related to the surface charge of the variant β -subunit. At pH 8.0, where α -subunits are at their isoelectric point and therefore lack significant net surface charge, differences in charge on the β -subunit no longer affect the rate of $\alpha\beta$ -dimer formation. These subunit competition experiments are in satisfactory agreement with a theoretical model based on the effect of smeared charge on the diffusion-limited association of macromolecules. As mentioned earlier, the overall rate of combination of α - and β -subunits is 1,000 times slower than the diffusion-limited reaction rate. Moreover, there is no significant difference in the rate of dissociation of $\alpha\beta$ -dimers of widely different charges ($\alpha\beta^N$, $\alpha\beta^A$, $\alpha\beta^C$). Taken together, these observations strongly suggest that hemoglobin assembles by the formation of an intermediate encounter complex ($\alpha \cdots \beta$) that can relax into the stable $\alpha\beta$ -dimer:

Fig 3. Subunit competition. Equimolar mixtures of normal (β^A) and a variant β -subunit (β^J , β^S , β^C) were mixed with increasing amounts of tritium-labeled α -subunits. At intracellular pH (7.2) these variant β -subunits in their native heme-intact state have net surface charges of -4.5 , -3.5 , -1.5 , and -0.5 , respectively. The products (Hb A and Hb X) were measured by high-performance liquid chromatography. The solid lines represent the computed theoretical fit for competitive recombination reactions between β^A and β^X , assuming that at low α -chain concentrations, the Hb X-Hb A ratio is a measure of the relative rates of assembly of $\alpha\beta^A$ and $\alpha\beta^X$ (data from Mrahet et al²⁹).

EFFECT OF SUBUNIT ASSEMBLY ON HEMOGLOBIN PHENOTYPE

This electrostatic model of hemoglobin assembly provides a sound explanation for why the levels of stable, positively charged β -globin variants in heterozygotes tend to be relatively low compared with Hb A and are further lowered in the presence of α -thalassemia. It also explains the converse observations on the negatively charged variants (see Fig 2). In addition, this model explains a number of other hematologic observations.

The pathophysiologic consequences of the sickling disorders are determined primarily by the concentration of Hb S in the patient's red cells.³⁴ Why do SC heterozygotes have a disease that is sometimes as severe as that of SS homozygotes, while AS heterozygotes are virtually free of clinical manifestations? There are two reasons why Hb S polymerizes more readily in SC than in AS red cells. First, because of potassium and water loss imposed by the presence of C hemoglobin,³⁵ SC red cells have a relatively higher concentration of total hemoglobin.^{36,37} Second, and of equal importance, the proportion of Hb S is 10% to 15% higher in SC red cells than in AS red cells.^{37,38} The latter finding can be explained by differences in the rates of subunit assembly. As shown in Fig 3, the relative rates of $\alpha\beta$ -dimer formation is $A > S > C$. These differences are reflected in the levels of hemoglobins in AS and SC red cells. The converse situation pertains when Hb S is inherited with a negatively charged β -globin variant. In these double heterozygotes, the proportion of Hb S is even lower, and thus the proportion of the variant is even higher than that found in association with Hb

A. For example, the proportion of Hb Pyrgos (β 83 Gly $\rightarrow$ Asp) was 62% in an S/Pyrgos double heterozygote, compared with 52% in relatives who were A/Pyrgos heterozygotes.³⁹ These findings are again fully consistent with the effect of surface charge on the assembly of normal and variant hemoglobins.

Measurement of minor hemoglobin components has been useful in the diagnosis of a number of hematologic disorders. Hb A₂ ($\alpha_2\delta_2$) normally constitutes about 2% of the hemolysate. This component is increased approximately twofold in β -thalassemia trait and decreased in various forms of α -thalassemia⁴⁰ as well as in two acquired disorders: iron deficiency^{40,41} and sideroblastic anemia.^{42,43} In the latter two conditions, a relative deficiency of α -globin synthesis has been noted in some studies.⁴³⁻⁴⁶ Therefore, they can be considered acquired forms of α -thalassemia. The δ -globin subunit is considerably more positively charged than is the β -subunit. Therefore, when the production of α -globin is limiting (α -thalassemia), the relative amount of Hb A₂ would be expected to decrease. In contrast, when α -subunits are present in excess, as in β -thalassemia, the small amount of δ -subunits that are produced should be fully titrated, and therefore Hb A₂ increases. This proposal is supported by competition experiments showing that α -subunits bind more avidly to β - than to δ -subunits.⁴⁷ The contribution of subunit competition to the formation of Hb A₂ provides a reasonable explanation for the slight elevation in Hb A₂ that has been noted in individuals with sickle trait (AS)⁴⁸ as well as in SS homozygotes who also have α -thalassemia.⁴⁹

Hb F ($\alpha_2\gamma_2$), the major hemoglobin component of the fetus, is normally replaced by Hb A by means of a switching mechanism that takes place during the latter part of gestation. Whatever Hb F that remains is compartmentalized in a restricted population of red cells. Elevations of Hb F in a variety of congenital and acquired disorders are generally proportional to the number of F cells that are produced. However, levels of Hb F could also be affected by differences in assembly. Because β - and γ -subunits differ considerably in primary structure (39 out of 146 residues), it is likely that factors other than charge affect their relative rates of binding to α -subunits. Because native heme-intact γ -subunits are difficult to isolate and work with, no competition experiments have been done. However, some recent clinical observations address this issue. In newborns, the proportion of Hb F is lower in those with α -thalassemia than in those having all four α -globin genes.⁵⁰ In addition, an individual heterozygous for deletion-type hereditary persistence of fetal hemoglobin was found to have only 7% Hb F when he had severe iron deficiency.⁵¹ Iron replacement resulted in increased synthesis of α -globin subunits as well as an increase in Hb F to a steady-state level of 25%. These hematologic observations suggest that α -subunits combine less readily with γ - than with β -subunits.

In keeping with this model of hemoglobin assembly are the observations that when AS and AE heterozygotes become iron deficient, the level of the positively charged variant hemoglobin drops markedly^{52,53} but, as with the patient described earlier, is readily corrected by iron replacement. It is likely in all these cases that the acquired α -thalassemia

intensifies the competition between normal and the variant subunit.

Although a large body of hematologic and experimental observations supports this model certain exceptions can be cited. For example, the level of Hb C in AC individuals is about the same as that of Hb S in those with sickle trait (Fig 2). Moreover, α -thalassemia has no effect on the proportion of S and C hemoglobin in individuals with SC decrease.⁵⁴ Thus, in vivo β^S and β^C compete about equally well for α -subunits, whereas in vitro (Fig 3) β^S combines about three times as readily as β^C . It is possible that mild instability of Hb S⁵⁵ is an independent contributor to the proportion of Hb S in circulating red cells.

TARGET CELLS

The surface charge of hemoglobin may impact on another phenotypic feature: red cell volume. One of the most commonly observed characteristics of "hemoglobinopathies" is the presence of target cells on dried blood films. This finding is accompanied by a shift to the right of the osmotic fragility curve indicative of a relative decrease in the ratio of cell volume to surface area. Target cells are prominent in the following commonly encountered genotypes: CC, AC, SS, EE, AE, and DD. In a rare homozygote with hemoglobin O-Arab, both target cells and a right-shifted osmotic fragility were noted.⁵⁶ All of these variants are positively charged. There is solid experimental evidence that hemoglobin binds to the inner surface of the red cell membrane by electrostatic interactions,⁵⁷⁻⁵⁹ probably to a negatively charged domain on the cytoplasmic side of the major integral membrane protein, Band 3. Therefore, it is likely that this binding is affected by

the surface charge of hemoglobin. Hb C binds more strongly than Hb A to the cytoplasmic surface of red cell membranes.⁶⁰ This "assembly" may be an integral part of a recently described pathway that causes leakage of potassium and water from red cells.³³ This pH-and-ionic strength-dependent pathway is active in CC red cells and is also readily observed in AC, SS,⁶¹ and EE red cells. Thus, the surface charge of hemoglobin may be a critical determinant of red cell volume and may explain the presence of cell dehydration and target cells that is such a prominent feature of the common positively charged variants.

BROADER IMPLICATIONS

The assembly of hemoglobin is apt to be relatively simple compared with that of other biologically important macromolecules. An array of biophysical probes is becoming available to investigate these important posttranslational events. Examples of particular interest to hematologists include (a) secreted proteins, such as immunoglobulin and factor VIII-von Willebrand factor; (b) membrane complexes, such as the T cell receptor for antigen and platelet membrane glycoproteins 2B-3A; (c) structural proteins such as the spectrin-actin-4.1 assembly in the red cell cytoskeleton; and (d) the complex variety of protein-DNA and protein-RNA interactions that regulate gene expression.

ACKNOWLEDGMENT

I am indebted to William Eaton, Melisenda McDonald, Nadir Mrabet, Joseph Shaeffer, and Attila Szabo for many enlightening discussions.

Evidence for Chemical Differences in HLA-DR Molecules on Autologous Acute Lymphoblastic Leukemia and B-Lymphoblastoid Cell Lines

By Lynn Graf and John M. Pesando

HLA-DR molecules on autologous acute lymphoblastic leukemia (ALL) and B-lymphoblastoid cell lines from two individuals were compared by immune precipitation and gel electrophoresis. Cells were surface labeled with ^{125}I and proteins immunoprecipitated with specific monoclonal antibodies (MoAb). Two electrophoretically distinct bands were found in the HLA-DR beta chain region on both ALL cell lines in contrast to only one on each of the autologous B-lymphoblastoid cell lines. Differences in the electrophoretic mobility of the alpha chains were also observed with ALL and B-lymphoblastoid cell lines from one individual. Preclearing of radiolabeled cell lysates with MoAb specific for HLA-DQ and -DP molecules demonstrated that the complexity of the HLA-DR pattern is not the result of

antibody cross-reactivity with alpha and beta chains from other class II products. Immunoprecipitation experiments indicated that two beta chain bands are observed with each of the parental HLA-DR molecules on the ALL but not the B-lymphoblastoid cell line from an HLA-DR3,7-positive individual. We conclude that the HLA-DR molecules expressed on ALL and B-lymphoblastoid cell lines from the same individual can differ chemically. Neuraminidase treatment reduced these electrophoretic differences, indicating that these molecules differ in their sialic acid content. Since small changes in class II molecules can profoundly alter cellular interactions, the functional significance of these differences requires further investigation.

CLASS I AND II MOLECULES of the major histocompatibility complex (MHC) serve as corecognition elements in antigen presentation to T lymphocytes. Small differences in these cell surface glycoproteins can profoundly affect their ability to mediate interactions among cells involved in the immune response.¹ Recent studies indicate that alterations in these molecules contribute to malignant behavior by interfering with the recognition of tumor cells by the immune system of the host.²⁻⁴

Class II molecules are polymorphic heterodimers comprised of heavy (alpha) and light (beta) chains having molecular weights of 33 to 35 kilodaltons (kd) and 26 to 31 kd, respectively. In an extensive series of experiments using indirect immunofluorescence and immunoprecipitation assays, we have previously shown that malignant B cells often fail to express one or more of the three types of class II molecules (HLA-DR, -DQ, and -DP) present on normal B lymphocytes.⁵ We now demonstrate by immunoprecipitation and gel electrophoresis that serologically identical HLA-DR molecules expressed on cell lines derived from autologous normal and malignant B cells from two individuals with acute lymphoblastic leukemia (ALL) are chemically distinct. These HLA-DR molecules differ in their sialic acid content, although we cannot rule out additional chemical differences at this time.

MATERIALS AND METHODS

Cell lines and antibodies. The autologous ALL (Laz 221 and NALM-6) and Epstein-Barr virus (EBV)-transformed normal B cell lines (Laz 388 and B85) have been described previously.⁵⁻⁷ The autologous nature of each pair of cell lines was confirmed by HLA typing with alloantisera by Dr Patrick Beatty of the Puget Sound Blood Center. Laz 221 and Laz 388 cells are HLA-DR1, DR5-, and DRw52-positive, while NALM-6 and B85 are DR3-, DR7-, and DRw52-positive. All cells were cultured in RPMI 1640 medium (GIBCO, Grand Island, NY) supplemented with 10% fetal bovine serum (Hyclone, Logan, UT). Class II molecules were identified by the following monoclonal antibodies (MoAb): HLA-DR (p4.1,⁸ I-2,⁹ ISCR3,¹⁰ 1-32, 7.2,¹¹ and SFR16-DR7M¹²); HLA-DQ (Leu 10,¹³ Genox 3.53,¹⁴ and 1-296); and HLA-DP (B7/21¹⁵) (specificities as discussed in Pesando and Graf⁵).

Cell surface labeling, immunoprecipitation, and gel electrophoresis. Cells were surface-labeled with ^{125}I (1 mCi/25 × 10⁶ cells)

using the lactoperoxidase method⁹ and lysed with Tris-HCl-buffered Triton X-100 (Sigma, St Louis). MoAb as hybridoma supernatants or ascites fluid were adsorbed to the appropriate matrix (Protein A-Sepharose, Pharmacia, Piscataway, NJ, or rabbit anti-mouse Ig Sepharose) overnight prior to addition of radiolabeled lysate. Class II molecules were immunoprecipitated and prepared for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) on 25-cm 10%- to 15%-gradient slab gels according to the method of Dobberstein et al.¹⁶ For sequential immunoprecipitations, lysate was first depleted of one antigen by four treatments with the same MoAb before being used for immunoprecipitation with additional MoAb.

Where indicated, immunoprecipitates were treated four times with 0.025U neuraminidase (*Vibrio cholerae*, Calbiochem, San Diego) over a period of six hours at 37 °C in 0.1 mol/L acetate buffer, pH 5.5, containing 9 mmol/L CaCl₂ prior to two-dimensional gel electrophoresis. Washed immunoprecipitates were separated by SDS-PAGE as described above. HLA-DR molecules were located with the aid of fluorescent marker proteins, excised, and analyzed by isoelectric focussing (IEF) at pH 5 to 8 as described by Shackelford and Strominger.¹⁷

RESULTS

Molecules identified by HLA-DR-, -DQ-, and -DP-specific MoAb were precipitated from surface-iodinated

Fig 1. Comparison of class II molecules on autologous ALL and B-lymphoblastoid cell lines by SDS-PAGE. The class II molecules from Laz 221 (lanes A through C) and Laz 388 (lanes D through F) cells were immunoprecipitated with the HLA-DP-specific MoAb B7/21 (lanes A and D), the HLA-DR-specific MoAb p4.1 (lanes B and E), and HLA-DQ-reactive MoAb Genox 3.53 (lanes C and F). 2×10^6 cell equivalents were used for each immunoprecipitation, and the autoradiogram was exposed 1 week. The varying intensity of these bands does not necessarily reflect the number of molecules expressed because of differences in the efficiency of iodination of different cell lines and molecules. Approximate molecular weights in kilodaltons are indicated on the left.

autologous ALL and B-lymphoblastoid cell lines (Figs 1 and 3). HLA-DR and -DP molecules were detected on both ALL and B-lymphoblastoid cell lines, whereas HLA-DQ molecules were detected only on B-lymphoblastoid cells, in agreement with our previous data.⁵ SDS-PAGE analysis of molecules on Laz 221 and Laz 388 cells (Fig 1) demonstrated the presence of two electrophoretically distinct HLA-DR beta chain bands of equal intensity on the ALL cell line versus a single beta chain on the autologous B-lymphoblastoid one. Side-by-side comparison also revealed slight differences in the electrophoretic mobility of the respective alpha chains. Four additional HLA-DR-specific MoAb (I-2, 1-32, 7.2, and ISCR3) produced identical results with these autologous cell lines (data not shown). Thus it is unlikely that the additional HLA-DR beta chain band is a protein that was nonspecifically coprecipitated by MoAb p4.1. Neither the position nor the intensity of any of the HLA-DR bands was altered by exhaustive preclearing of the radiolabeled lysate with MoAb specific for either HLA-DQ (Genox 3.53) or HLA-DP (B7/21) molecules, demonstrating that cross-reactivity of HLA-DR antibodies with other class II products was not responsible for the complexity of the pattern of HLA-DR molecules on the ALL cells (Fig 2). There may also be slight differences in the higher molecular-weight region of the HLA-DP molecules radiolabeled on these two cell lines, but the poor resolution of HLA-DP beta chain(s) on Laz 221, a consistent finding with this cell line, did not permit an exact comparison. HLA-DP alpha chains are not radiolabeled by surface iodination.¹⁵

Figure 3 shows a similar comparison of a second ALL cell line, NALM-6, with its autologous B-lymphoblastoid cell line B85. HLA-DR-specific MoAb again immunoprecipitated what appear to be two distinct bands in the beta chain region in the ALL cells, with the upper band being fainter

Fig 2. Sequential immunoprecipitations with anti-class II MoAb. Lysates from surface-iodinated Laz 221 cells were precleared in parallel with MoAb specific for HLA-DQ (Genox 3.53, lanes A through C), HLA-DP (B7/21, lanes D through F) or HLA-DR (p4.1, lanes G through I) and split into three aliquots which were used for immunoprecipitation with the same three antibodies. Lanes A, D, and G: Genox 3.53; lanes B, E, and H: p4.1; lanes C, F, and I: B7/21.

than the lower one. A shorter exposure of this autoradiograph (data not shown) confirmed the appearance of only a single HLA-DR beta chain band on the B85 cell line (lanes F and G).

Both pairs of autologous cell lines are heterozygous for HLA-DR molecules (see Materials and Methods). Reactivity of alloantisera indicate that NALM-6 and B85 are both HLA-DR3,7-positive. To determine the contributions of these two parental HLA-DR haplotypes to the observed electrophoretic patterns, we isolated and studied these molecules using the polymorphic HLA-DR-specific MoAb I-2 and SFR16-DR7M. I-2 reacts with cells of all HLA-DR types except DR7.⁹ Thus it should only react with HLA-DR3 molecules on NALM-6 and B85. In contrast, SFR16-DR7M only binds to molecules that carry the HLA-DR7 serologic specificity.¹² Immunoprecipitation with these two MoAb (Fig 4) indicated that HLA-DR3 and -DR7 molecules are expressed on both of these cell lines. Moreover, the beta chains of both the HLA-DR3 and -DR7 molecules appeared

Fig 3. Class II molecules on the NALM-6 (lanes A through E) and B85 (lanes F through J) cell lines were detected by immunoprecipitation with MoAb B7/21 (lanes A and J); HLA-DR-specific MoAb p4.1 (lanes B and F) and I-2 (lanes C and G); and HLA-DQ-reactive MoAb Leu 10 (lanes D and H) and 1-296 (lanes E and I).

Fig 4. Analysis of HLA-DR molecules immunoprecipitated from surface-iodinated NALM-6 (lanes A and B) and B85 (lanes C and D) cells by polymorphic MoAb. MoAb I-2, which reacts only with DR3 molecules in these cells, was used for lanes A and C. The DR7-specific MoAb SRF16-DR7M was used for samples in lanes B and D.

as doublets in the ALL cell line and as singlets in the B-lymphoblastoid line.

Since both the alpha and beta chains of HLA-DR molecules are glycosylated,¹⁷ we evaluated the possible role of sialic acid residues in producing the apparent molecular-weight differences and doublet patterns observed by SDS-PAGE. Immunoprecipitates from all four cell lines were treated with neuraminidase (0.1 U total) or sham-treated and analyzed by SDS-PAGE (Fig 5). Treatment with neuraminidase reduced the apparent molecular weight of both the alpha and beta chain(s) on all cell lines, but some differences remained between the HLA-DR molecules from autologous cell populations. Treatment of the sample shown in lane E with twice the standard amount of neuraminidase produced no further changes detectable in this gel system.

Fig 5. Effect of neuraminidase treatment. HLA-DR molecules were immunoprecipitated with the HLA-DR-specific MoAb p4.1 from Laz 221 (A and C), Laz 388 (B, D, and E), NALM-6 (F and H) and B85 (G and I) cell lines. Samples were sham-treated (A, B, F, and G) or treated with 0.1 U neuraminidase (C, D, H, and I). Sample E from Laz 388 cells was incubated with 0.2 U neuraminidase.

Fig 6. Two-dimensional gel electrophoresis of HLA-DR molecules immunoprecipitated from Laz 221 (ALL) and Laz 388 (NML) cells with MoAb ISCR3. The samples with (A) or without (B) neuraminidase treatment were separated by SDS-PAGE, then analyzed on an isoelectric focussing gel, pH 5 to 8. Brackets indicate the approximate position of alpha and beta chains. The acidic pole is to the right and the basic pole to the left.

HLA-DR molecules from the Laz 221 and Laz 388 cell lines (DR1,5; DRw52) were also analyzed with and without neuraminidase treatment by two-dimensional gel electrophoresis according to the method of Shackelford and Strominger¹⁸ (Fig 6). The MoAb used (ISCR3) has been shown to react with both the DR1 and DR5 haplotypes. Two rows of spots in the beta chain region, one above the other and with the upper set shifted slightly to the acidic pole, were observed in samples of the ALL line that were processed without neuraminidase treatment (Fig 6B). Only a single row of spots was present in HLA-DR molecules from corresponding samples from the B-lymphoblastoid cells. The desialylated HLA-DR beta chains on these autologous cell lines (Fig 6A) appeared to be quite similar.

HLA-DR molecules immunoprecipitated from NALM-6 and B85 cells with the I-2 and SFR16-DR7M MoAb were also treated with neuraminidase and analyzed by two dimensional gel electrophoresis (Fig 7). The HLA-DR7 beta chain spots are more acidic than those from HLA-DR3 molecules. This confirmed that the two MoAb react with different HLA-DR molecules. The desialylated HLA-DR beta chains on the autologous ALL and B-lymphoblastoid cell lines again appeared to be quite similar. Minor differences remaining could result either from incomplete removal of sialic acid residues or from further as yet unidentified glycosylation differences.

DISCUSSION

These electrophoresis studies document chemical differences in the HLA-DR molecules expressed on autologous malignant versus EBV-transformed B cell lines from two individuals with ALL. The most significant finding is the presence of two electrophoretically distinct bands in the beta

Fig 7. Two-dimensional gel electrophoresis of neuraminidase treated HLA-DR molecules from NALM-6 (ALL) and B85 (NML) cells. The HLA-DR3-specific MoAb I-2 and the HLA-DR7-specific MoAb SFR16-DR7M were used to study both of these cell lines. All four samples were compared simultaneously as in Fig 6.

chain region of HLA-DR molecules from ALL but not B-lymphoblastoid cell lines. This pattern is observed with multiple monomorphic HLA-DR-specific MoAb. Use of polymorphic HLA-DR-specific MoAb indicates that two beta chain bands are found with both of the parental HLA-DR molecules on ALL cells from an HLA-DR 3,7-positive individual. We cannot yet determine what role, if any, HLA-DR beta chains carrying the alloantiserum-defined DRw52 specificity play in the electrophoretic patterns observed. Immunodepletion studies employing HLA-DQ- and -DP-specific MoAb indicate that the unique appearance of HLA-DR molecules on ALL cells is not due to serologic cross-reactivity with the alpha or beta chains of other class II molecules. While we do not know how closely the HLA-DR molecules on the two types of B cell lines resemble those of normal and malignant B cells occurring in vivo, this is the first report describing differences in the HLA-DR molecules on autologous cells within the same lineage.

If the genes encoding class II molecules are identical in normal and leukemic B cells from the same individual, then differences in individual molecules expressed on the cell surface most likely reflect unique post-translational modifications of common precursor proteins or variable surface expression of shared molecules. Our studies indicate that the HLA-DR molecules from these two cell types differ in their sialic acid content. Whether additional glycosylation differences also play a role in the observed unique electrophoretic patterns is unclear. Molecular weight variations between the alpha chains of HLA-DR molecules on a human melanoma line and its autologous B-lymphoblastoid cell line were found to reflect unique carbohydrate structures including but not limited to sialic acid.¹⁹

Small changes in class II molecules can have profound effects on the process of self-recognition. Thus the spontaneous bm12 mutant of the mouse demonstrates mixed lymphocyte reactivity with cells of the parent strain, a new pattern of MHC-restricted antigen presentation, and altered binding of class II-specific MoAb.²⁰ The class II molecules of the parent and mutant strains differ by only three amino acids.²¹ Single amino acid substitutions in murine class II molecules can similarly alter their capacity to present antigens to T lymphocytes.^{1,22,23} Cowing et al²⁴⁻²⁶ report that differences in the carbohydrate moieties on class II molecules can also affect their function. The increased number of sialic acid residues on class II molecules from resting B lymphocytes versus accessory cells from mouse spleen appears to impair the ability of the former cells to activate T lymphocytes. Treatment of splenic B cells with neuraminidase to remove sialic acid residues restores their ability to trigger T cell proliferation. These studies suggest that the chemical differences that we have observed in the HLA-DR molecules on autologous normal and malignant human B cell lines might be functionally significant. Preliminary experiments in our laboratory indicate that these autologous cell lines differ in their ability to present cell-associated antigens to T lymphocytes.

Loss of Interleukin-2 Requirement for the Generation of T Colonies Defines an Early Event of Human T-Lymphotropic Virus Type I Infection

By Madeleine Duc Dodon and Louis Gazzolo

Accessory cells and/or soluble factors, together with interleukin 2 (IL2), are required for the proliferation and differentiation of phytohemagglutinin (PHA)-activated T lymphocytes. Human T-lymphotropic virus, type I (HTLV-I), a human retrovirus isolated from patients with adult T cell leukemia, can transform T cells in vitro. We investigated the role of HTLV-I-transformed T cell lines as accessory cells in promoting the growth of T colony-forming cells. We found that T cells isolated by E rosetting and then activated with PHA, when seeded with as few as 5×10^3 irradiated HTLV-I-producing cells, could generate colonies in the absence of IL2. We analyzed further the effects of HTLV-I virions on T colony formation. Infection of T cells with semipurified HTLV-I viral particles promoted colony formation, in the absence of IL2, of accessory cells or soluble factors. The same results were obtained either

with monocyte-depleted T lymphocytes, or with T4 or T8 lymphocytes. Furthermore, T lymphocytes in the presence of heat-inactivated HTLV-I (devoid of replicative potential) could form colonies independently of IL2. Finally, experiments with sera positive for HTLV-I antibodies (to abolish binding of viral particles to cellular receptors) indicated that HTLV-I promoted IL2-independent colony formation, only by "touching" T colony-forming cells. These results taken together demonstrate that the loss of the exogenous IL2 (and other growth-helping factors) requirement defines an early event of HTLV-I infection. The results also suggest that viral attachment to T cells possibly supplies an accessory function triggering autocrine secretion of IL2 by these cells.

THE IDENTIFICATION, isolation and characterization of growth factors have provided new and challenging insights on the mechanisms governing cellular proliferation and differentiation. In particular, lymphokines produced by antigen- or mitogen-activated T lymphocytes are responsible for the multiple effects of cellular immune reactions, by regulating the differentiation of lymphoid cells. Among these lymphokines, IL2 (formerly known as T cell growth factor¹) is required for the amplification of T cell populations. Upon exposure to antigens, lectins and other mitogenic signals, T lymphocytes express cell surface IL2 receptors.² Such activated T cells are now able to produce IL2 which, after interaction with specific high-affinity IL2 receptors, stimulates the growth of these cells.^{3,4} Furthermore, the proliferative response of T cells to activating agents is effective only in the presence of accessory cells.

Studies on the generation of colonies by T cells have provided much valuable information on the parameters controlling T cell proliferation in vitro.⁵⁻⁸ Thus, IL2 and accessory cells are both required for PHA-induced T colony formation. Accessory cells, which include monocytes, T cells, and B cells of normal and leukemic origin, are implicated both in the induction of IL2 synthesis and in the expression of functional IL2 receptors allowing IL2 responsiveness by the

T colony-forming cells.⁸ The same colony-forming ability was also observed when soluble factors released by accessory cells were incorporated in the colony medium.⁶

Because it leads to the amplification of activated T cells, IL2 has been decisive in isolating and characterizing human T-lymphotropic retroviruses (HTLV),⁹ such as HTLV-I associated with T cell leukemia (ATL) and LAV (lymphadenopathy-associated virus)/HTLV-III associated with the acquired immunodeficiency syndrome.^{10,11}

HTLV-I is able to transform T cells in vitro. T lymphocytes obtained from peripheral blood, umbilical cord blood or bone marrow and infected with HTLV-I are in most cases grown in the presence of IL2 until the overgrowth by transformed T cells which have become independent on this growth factor, several weeks after infection.^{12,13} T cell lines derived from leukemic donors and T cell lines obtained after in vitro infection both continue to express IL2 receptors. Moreover, the majority of these HTLV-I-transformed cell lines do not release IL2, while they are still able to secrete a large variety of other lymphokines.¹⁴

Several studies have shown that infection of T cells by HTLV-I causes impaired immune functions of T cells.¹⁵ Once infected, these cells might also disturb the growth of normal T cells. Preliminary observations on the role of HTLV-I transformed T cell lines as accessory cells led us to investigate further the involvement of viral particles in T colony formation. The results reported in this paper indicate that HTLV-I infected cells and HTLV-I virions are both able to induce the proliferation of T colony-forming cells in the absence of exogenous IL2.

MATERIALS AND METHODS

Cell separation. Peripheral blood was collected from normal healthy volunteers. Leukocytes (PBL) were obtained after buffy coat sedimentation at unit gravity for 45 minutes using a 1% methylcellulose solution. Mononuclear cells (MNC) were separated by Ficoll-Hypaque density centrifugation ($d = 1.077 \text{ g/mL}$), washed twice with RPMI 1640 and resuspended in RPMI supplemented with 10% heat-inactivated fetal calf serum (FCS). T cell separation was carried out according to Madsen et al¹⁶ by rosetting with 2-aminoethylisothiuronium bromide (AET)-treated sheep red

blood cells (SRBC) and a second density centrifugation was performed through Ficoll-Hypaque. The E rosette-depleted cells (E^-) were collected from the interface, and the E rosette-enriched cells (E^+) were recovered from the pellet, after hypotonic lysis of the SRBC in 0.15 mol/L ammonium chloride. The E^+ cell population contained a majority of T cells (over 95%), as assessed by immunofluorescent labeling with OKT3 monoclonal antibody, and about 5% of nonspecific esterase-positive monocytes and of surface Ig-positive cells.

In specific experiments, purified T lymphocytes were obtained by using a three-step procedure. MNC were depleted of adherent cells by one-hour incubation in a plastic culture flask, followed by the elimination of phagocytic cells by carbonyl iron ingestion at 37 °C for one hour and passage over a magnet. T lymphocytes were then isolated by overnight incubation with AET-treated SRBC and centrifugation over a Ficoll-Hypaque gradient. Almost pure T cells (OKT3-positive) were recovered from the pellet after lysis of the SRBC. These T cells were further separated in T4 or T8 lymphocytes by treatment with the OKT8 or OKT4 monoclonal antibodies, respectively, and then appropriately diluted newborn rabbit complement, with the use of a cytotoxic assay.

Monocytes were prepared after adherence of MNC to plastic culture flasks. After elimination of the nonadherent cells and extensive washings, adherent cells were detected after a 20-minute incubation in 3 mmol/L EDTA. This cell population was found to contain more than 95% nonspecific esterase-positive monocytes and less than 3% OKT3 cells.

T colony-forming assay. The T colony assay was performed according to a previously described technique.⁸ Cultures were prepared in 35-mm plastic Petri dishes, by using two layers of semisolid agar medium of 1 mL each. The underlayer contained 0.45% agar, 10% of a mixture of human AB serum and FCS, 40 μ g of phytohemagglutinin (PHA)-P (Wellcome) and 10% lectin-free IL2 (Cellular Products) in α -minimum essential medium (MEM). This was overlaid with 1 mL of 0.30% agar in α -MEM containing 2×10^5 E^+ cells, 1×10^6 X-irradiated accessory cells (PBL or E^- cells), or conditioned medium from Raji cells, to a final concentration of 40%. Plates were then incubated for seven days at 37 °C in 5% CO₂-humidified atmosphere. On days 1 through 3, colonies were not generally found. On days 4 to 5 after seeding, an increase in the number of colonies was observed. This number reached a peak on day 7 or 8 at which time they were counted using a Nikon inverted microscope. Only clusters containing more than 40 cells were scored as colonies. Each assay was performed in duplicate. The results of at least five separate experiments were expressed as mean $\pm$ SD.

Cell lines. All cell lines (kindly provided by Dr R.C. Gallo, Bethesda, MD) used in this study were grown in RPMI 1640 supplemented with 10% FCS. The HTLV-I-transformed T cell lines included HUT102¹⁷ (derived from a patient with a cutaneous T cell lymphoma) MT2,¹⁸ C91/PL,¹⁹ and C81-66/45,²⁰ all obtained after transformation of cord blood cells, cocultivated with HTLV-I-producing cells. All these transformed HTLV-I T cell lines express the 42-kilodalton HTLV-I *x-lor* protein product correlated with *trans*-activation of the long terminal repeat.^{21,22} However, the C81-66/45 cell line is nonproductively infected with HTLV-I, since these cells do not express *gag* antigens, and reverse transcriptase activity and viral particles were not detected in culture medium.²⁰ Finally, the H9 clone of the HT lymphoblastoid cell line was also used in this study, together with LAV/HTLV-III-infected H9 cells.¹¹ Before addition to the upper layer with E^+ cells, these cell lines were extensively washed, resuspended in medium and X-irradiated at 6,000 R.

The conditioned medium from Raji cells (a B cell line) was obtained by cultivating these cells in RPMI 1640 supplemented with 10% FCS for four days at 37 °C. The supernatant was then collected,

pooled after centrifugation at 1,000 g for ten minutes and filtered through a 0.45 μ m membrane filter. It was stored at -20 °C.

Viral infection of cells. Media containing either HTLV-I or LAV/HTLV-III particles were harvested from the different cells listed above. Following removal of the cells by low-speed centrifugation, the virus containing supernatant was concentrated 20-fold by centrifuging for three hours at 32,000 g in a Beckman type 35 rotor and resuspending the viral pellets in an appropriate volume of RPMI 1640 supplemented with 10% FCS. The virus was frozen at -70 °C, until infection of E^+ cells: 100 μ L of viral suspension and 100 μ L of E^+ cell suspension (at a concentration of 4×10^6 cells per mL) were mixed in a glass tube and incubated at room temperature for 30 minutes. At the end of the incubation period, cells were added to 1,800 μ L of agar medium and delivered into two 35-mm dishes, on the top of the hard agar layer. The virus was heat-inactivated by incubation at 56 °C for one hour, just before infection of E^+ cells.

Sera to be used in neutralization assays were heat-inactivated at 56 °C for 30 minutes. For each assay, one volume of viral suspension and one volume of serum at the desired dilution were mixed and incubated for one hour at room temperature, just before infection of E^+ cells.

RESULTS

Effect of HTLV-I-producing lines on T cell colony formation. As indicated in Materials and Methods, the presence of accessory cells or that of soluble factors produced by them was found to be mandatory for colony formation by E^+ cells under our experimental conditions. No colony formation was observed when E^- cells were incubated under the same assay conditions.

Experiments to ascertain the role of HTLV-I-producing T cell lines as accessory cells in T colony formation were performed in the absence or in the presence of IL2. In fact, some of the HTLV-I-transformed cells (MT2, HUT102) were found to secrete low amounts of IL2²³ (data not shown). As indicated in Table 1, it was surprising to find that IL2 was not necessary for colony formation when irradiated HTLV-I-producing cells were seeded in the upper layer. In fact, T colony-forming cells proliferated when as few as 5×10^3

Table 1. Effect of HTLV-I-Transformed T Cell Lines as Accessory Cells on the Number of Colonies Formed by E^+ Cells, in the Absence of IL2

Irradiated Accessory Cells	HTLV-I Production	Number of Cells	Number of Colonies/Plate
Transformed with HTLV-I			
C91/PL	+	5 × 10 ³	1312 ± 187
		20 × 10 ³	1474 ± 225
MT2	+	5 × 10 ³	2030 ± 155
		20 × 10 ³	TMTC
HUT102	+	5 × 10 ³	1225 ± 72
		20 × 10 ³	1737 ± 75
C81-66/45	—	5 × 10 ³	0
		20 × 10 ³	0
Not transformed with HTLV-I			
H9	—	5 × 10 ³	0
		20 × 10 ³	0
Peripheral blood leucocytes	—	5 × 10 ³	0
		20 × 10 ³	0

Accessory cells were X-irradiated at 6,000 R and then seeded in the agar upper layer together with 2×10^5 E^+ cells. Data expressed as mean $\pm$ SD. TMTC, too many to count.

irradiated cells were cocultured with them. With the same number of irradiated normal PBL, colony formation was not observed. The majority of colonies obtained in the presence of irradiated HTLV-I-transformed cells were larger and contained more than 100 cells. That explains why in some cultures T colonies were too numerous to count when 20×10^3 irradiated transformed cells were seeded. In addition, overgrowth of the cultures in some dishes did not favor the development of colonies. The same was true when IL2 was added to these cultures (data not shown).

Only cells transformed by and producing HTLV-I were able to cooperate in the colony growth. The lymphoblastoid T cells (H9, not infected by HTLV-I) and C81-66/45 cells (which are transformed by HTLV-I but defective in the replication of the virus) did not promote colony formation when seeded at 5×10^3 cells/dish. These results suggest that generation of T colonies in the presence of HTLV-I-producing cells, but in the absence of exogenous IL2, may be accounted for by viral particles and/or viral antigens released by these cells.

HTLV-I infection induces T colony formation in the absence of IL2 and monocytes. To test this hypothesis, virus was concentrated from the culture supernatant of one HTLV-I-producing cell line (C91/PL). One volume of the viral preparation was added to one volume of the E⁺ cell suspension. After a 30-minute incubation at room temperature, cells were seeded into the agar upper layer at three different concentrations. The results of a representative experiment are shown in Fig 1. Under standard conditions in which HTLV-I-treated E⁺ cells were seeded at 2×10^5 cells/dish, T cell colony formation was observed in the absence of added IL2. No colony was detected in virus-untreated cultures (control) seeded at this concentration. At lower concentrations of HTLV-I-infected E⁺ cells (1×10^5 cells/dish), there was no promotion of colony growth in the absence of IL2. Only in control E⁺ cultures with more than 3×10^5 cells/dish were few colonies detected when IL2 was

Fig 1. T colony formation by uninfected E⁺ cells and E⁺ cells infected by HTLV-I (harvested from the medium of C91/PL cells, and concentrated 20 times). E⁺ cells were seeded in the agar upper layer, at three different cell concentrations, in the presence or absence of IL2. PHA (40 μ g/mL) and IL2 (1 U/mL) were added in the agar underlayer. Raji conditioned medium was added in the agar upper layer, at a final concentration of 40%. Colony numbers are expressed as mean $\pm$ SD.

omitted. This low number of colonies may reflect the endogenous production of IL2. It should be noted that at this latter cell density (3×10^5), in the absence of exogenous IL2, colonies in HTLV-I-treated cultures were 30 times more numerous than those found in control cultures (6,000 to 200, respectively).

When IL2 was added in the medium, colonies were observed with control as well as with virus-treated cells. However, the number of colonies in HTLV-I-treated cultures was about twofold higher than that in control cultures. Once again, colonies observed in E⁺ cultures incubated with virus in the absence of IL2 were larger than those in control cultures, grown in the presence of IL2. In the absence of PHA, HTLV-I-treated T lymphocytes as well as control T lymphocytes failed to generate colonies.

Further results shown in Fig 2 indicate that (1) no modification in the colony growth was noted when the virus-treated cells were seeded in the presence or absence of conditioned medium (Fig 2A); (2) the number of colonies obtained was proportional to the amount of virus added (Fig 2B); no colony formation could be demonstrated in the virus-free supernatant (obtained after high-speed centrifugation of the C91/PL growth medium (Fig 2C); (3) HTLV-I viral particles concentrated from the culture fluid of other HTLV-I-producing cell lines induced colony formation; conversely, LAV/HTLV-III was unable to promote colony formation without IL2 (Fig 2D); after addition of IL2, the same number of colonies as in the control cultures was observed with LAV/HTLV-III infected T cells (data not shown).

Phenotypic characterization of the colony cells was performed after mass harvesting the colonies of the agar culture. The membrane phenotype studies indicated that colony cells consisted of a mixture of cells bearing either the epitope T4 or T8.

Experiments described above were performed using E⁺ cells incubated with HTLV-I. This cell population was found

Fig 2. T colony formation, in the absence of IL2: (A) by E⁺ cells infected with HTLV-I (from C91/PL cells), with and without Raji conditioned medium; (B) by E⁺ cells infected with HTLV-I from C91/PL cells, as a dose response relationship with the amount of added virus; (C) by E⁺ cells infected with HTLV-I obtained after low-speed (1x) or high-speed centrifugation (SPN) of C91/PL medium; and (D) by E⁺ cell infected by HTLV-I harvested from two other HTLV-I-transformed cell lines (HUT102 and MT2) or with LAV/HTLV-III, harvested from the medium of H9/HTLV-III cells.

to contain a low percentage of monocytes. To determine whether monocytes were essential to the IL2-independent colony formation, experiments were performed on monocyte-depleted T lymphocytes. It was found that purified T lymphocytes incubated with HTLV-I were still able to generate colonies in the absence of exogenous IL2. However, the addition of 50,000 uninfected monocytes in the agar upper layer was followed by an increase in the number of colonies. The same increase in percentage (around 64%) was observed when uninfected purified T cells were seeded in presence of monocytes (Fig 3).

Finally, it was observed that T colony-forming cells, recruited among monocyte-depleted T4 or T8 lymphocytes, are able to proliferate in the absence of IL2, after incubation with HTLV-I (Fig 3). However, there were twice as many colonies generated with T4 lymphocytes as with those bearing the T8 epitope. Once again, a significant increase in the number of colonies followed the addition of monocytes.

In conclusion, incubation of T colony-forming cells with HTLV-I viral particles promotes a colony-forming ability independent of exogenous IL2, within seven days after plating. Moreover, monocytes, although favoring T colony formation, are not required for the IL2-independent colony generation promoted by HTLV-I.

Binding of HTLV-I particles to T cells is sufficient for colony formation independent of IL2. HTLV-I antigen p19 could not be detected in colony cells, indicating that viral replication was not taking place in these cells during the short time of colony formation. These results lead us to anticipate that T colony ability promoted by HTLV-I infection may not be linked to viral integration and replication,

Fig 3. Effect of monocytes on T colony formation by purified (monocyte-depleted) T lymphocytes either uninfected or infected with HTLV-I from C91/PL cells, or by T4 or T8 lymphocytes infected with this virus. Monocytes freshly prepared from the same peripheral blood were added at a density of 50,000 per plate, in the agar upper layer containing 40% of Raji conditioned medium. Colony numbers are expressed as mean $\pm$ SD.

but would follow an early event, such as the binding of HTLV-I virions to the surface of T colony-forming cells.

It is well established that early events in the infection of cells by virus, such as binding and penetration, are mediated by specific viral receptors on the surface of target cells. As assayed by flow cytometry, viral receptors of HTLV-I are more numerous on human T lymphocytes than on B lymphocytes.²⁴ To verify that the induction of T colony formation by HTLV-I particles could be mediated by binding of the virus to receptors on T colony-forming cells, viral particles were heat-inactivated by incubating them at 56 °C for one hour. After this treatment, which inhibits their replicative ability, viral particles were mixed with T cells. Under these conditions, the number and the size of colonies obtained after incubation with heat-treated virus were found to be the same as that observed with heat-untreated virus (Table 2). So, abolishing the replicative potential of the virus did not impair IL2-independent T colony proliferation.

Experiments were then performed to prevent the binding of viral particles to T cells. HTLV-I virions were incubated with sera from two ATL patients. The sera contained specific antibodies against HTLV-I (as determined by enzyme-linked immunosorbent assay [ELISA] and competition assays), and probably reacted with envelope and core polypeptides of the virus, as demonstrated by previous studies.^{25,26} As shown in Table 2, colony formation in the absence of IL2 was inhibited in a dilution-dependent manner by serum A. A significant inhibition was observed in serum B only when it was used undiluted. No such inhibition was observed with an HTLV-I seronegative serum from one individual living in the same endemic area. These results suggest that antibodies present in the sera from ATL patients mask viral antigenic determinants on the envelope of the particles and prevent their binding to T colony-forming cells. The results of these experiments indicate that events leading to IL2-independent T colony formation appear to follow the attachment of HTLV-I to T cells.

Table 2. Effect of Heat-Inactivated HTLV-I and Neutralized HTLV-I on the Number of Colonies Formed by E⁺ Cells, in the Absence of IL2

Treatment Prior Infection	Number of Colonies /Plate	Percentage of Inhibition %
None	2212 $\pm$ 138	—
Heat-inactivated	2074 $\pm$ 513	—
Incubated with		
HTLV-I-negative serum, undiluted	2081 $\pm$ 181	—
HTLV-I-positive serum A		
undiluted	31 $\pm$ 19	98.5
diluted 1:2	381 $\pm$ 6	81.7
diluted 1:10	1756 $\pm$ 69	15.7
HTLV-I positive serum B		
undiluted	1356 $\pm$ 169	34.9
diluted 1:2	2143 $\pm$ 56	—
diluted 1:10	2525 $\pm$ 50	—

HTLV-I was heat-inactivated at 56 °C for one hour just before infection of E⁺ cells. Incubation of HTLV-I with serum was carried out at room temperature for one hour just before infection of E⁺ cells. 2 $\times$ 10⁵ HTLV-I-infected cells were seeded per plate. Data expressed as mean $\pm$ SD.

DISCUSSION

Identification and characterization of IL2 has allowed the development of specific and well-controlled assays to study the *in vitro* proliferation and differentiation of T lymphocytes.¹⁻⁴ Among these assays, the T colony assay consisting of culturing either PBL or purified T cells in agar or methylcellulose has permitted the identification of a T cell population endowed with the capacity to form colonies.^{5-8,27} Two prerequisites for a high efficiency of colony formation by T cells are the addition of exogenous IL2 and the presence of accessory cells.

Results reported in this paper indicate that a subset of T colony-forming cells, present in either E⁺ or monocyte-depleted T cells, T4 lymphocytes, or T8 lymphocytes, is able to proliferate in semisolid agar independently of IL2 and accessory cells after contact with HTLV-I. Heat-inactivated virus is also able to induce colony growth independently of IL2. Furthermore, the inhibition of colony formation by T cells with HTLV-I and pretreated with ATL patients' sera containing antibodies to HTLV-I underlines the direct involvement of viral particles in promoting colony formation. As expected, colony formation was not observed with virus-untreated T cells, unless IL2 and accessory cells (or soluble factors produced by these cells) were added to the culture colony medium. These results therefore indicate that inactivated HTLV-I particles or viral glycoproteins are sufficient to promote T colony growth in the absence of any added growth factor. Previous studies^{12,13} on the transforming effects of HTLV-I have shown that T lymphocytes from cord blood or peripheral blood infected with HTLV-I, after cocultivation with irradiated HTLV-I-producing cells, were also able to grow *in vitro* in the absence of IL2. However, this autonomous growth (transforming effect) takes place only several weeks after initiation of the coculture. These observations are different from those reported in this paper, which demonstrate the ability of T colony-forming cells to proliferate independently of extrinsic IL2 within one week after virus addition.

Further experiments with monoclonal antibodies directed against the viral envelope glycoprotein (gp46) are needed to determine whether the viral neutralizing epitope is involved in the IL2-independent proliferation. Moreover, it will be of interest to define at what level on the T cell membrane HTLV-I is acting to trigger cell proliferation. As already mentioned by McGrath and Weissman²⁸ in a study on the relationship of normal immune receptors to retrovirus lymphomagenesis, it is reasonable to consider that HTLV-I is acting at the level of cell surface receptor complexes leading to the activation of the gene program required for T cell proliferation. Several receptors on the surface of T lymphocytes have been implicated in the activation and proliferation of these cells *in vitro*. Among these signals transducing receptors, the CD3-T cell receptor complex and the CD2 E-rosette receptor are mitogenic for T cells upon reaction with specific antibodies recognizing these structures.^{4,29-31} Whether HTLV-I receptors are identical to those surface receptors or are located close to them remains to be investigated.

The finding that T colony formation is independent of

exogenous IL2 suggests that T cell proliferation is induced through one of two mechanisms. The first is related to the direct activation of protein kinase C in the cell membrane, as already described, with PBL treated with the tumor promoter teleocidin.³² The second mechanism is linked to the autocrine secretion of IL2 by T cells in response to HTLV-I. In fact, the lack of T lymphocyte proliferation observed when HTLV-I-treated T cells were seeded at low concentrations might be secondary to their inability to produce sufficient endogenous IL2 (Fig 1).

Spontaneous T cell colony-forming ability has already been described in immature T cells derived from the peripheral blood of patients with T acute lymphoblastic leukemia.³³ Such cells were able to proliferate in methylcellulose in the absence of added growth factors or of mitogenic stimulation, but were partially dependent on factors released by mature T cells. However, it cannot be ruled out that the ability to form T colonies displayed by the leukemic cells may be the consequence of the leukemic process, which interferes with the mechanisms regulating normal proliferation and differentiation.

As underlined above, HTLV-I isolated from the peripheral blood of ATL patients is able to transform T cells *in vitro*. The other known human retrovirus, LAV/HTLV-III, was isolated from the peripheral blood of patients with the acquired immunodeficiency syndrome. This virus replicates exclusively in a subset of T cells, ie, helper/inducer cells with the CD4 phenotype.³⁴⁻³⁶ In contrast to HTLV-I, LAV/HTLV-III is unable to induce T colony formation in the absence of IL2. It is noteworthy that the CD4 epitope, which may be the receptor for this virus,^{34,35} is not involved in T cell activation, since perturbation of the CD4 molecules delivers a negative signal to T lymphocytes.³⁷

The growth of T cells in the absence of exogenous IL2 as reported here underlines an early effect of HTLV-I viral particles on target cells. The fact that such an effect occurs within seven days after the addition of HTLV-I is of paramount importance for the understanding of the mechanisms involved in viral-induced proliferation. Thus, the colony formation induced by HTLV-I in the absence of added IL2 may be considered as a preleukemic event favoring viral integration and viral replication in actively dividing T cells.

ACKNOWLEDGMENT

We thank Laure Coulombel, Marjorie Robert-Guroff, Jacques Bertoglio and Carlo Moscovici for critically reading the manuscript and for valuable discussions. We are also grateful to Didier Fradelizi for his generous gift of interleukin 2 and Jean Pierre Farcet for his helpful suggestions.

Human GM-CSF Primes Neutrophils for Enhanced Oxidative Metabolism in Response to the Major Physiological Chemoattractants

By Richard H. Weisbart, Luz Kwan, David W. Golde, and Judith C. Gasson

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a T cell-derived lymphokine which induces hematopoietic precursor cells to proliferate in vitro and differentiate to neutrophils and macrophages. GM-CSF also inhibits the motility of mature neutrophils (NIF-T activity), and primes neutrophils to enhance oxidative metabolism in response to the bacterial chemoattractant, *N*-formyl-methionyl-leucyl-phenylalanine (f-MLP). The present study was designed to determine whether this lymphokine also enhances neutrophil oxidative metabolism in response to the other major physiological chemoattractants which include complement-derived C5a, and the 5-lipoxygenation product of arachidonic acid, leukotriene B₄ (LTB₄). Su-

peroxide anion production was measured as superoxide dismutase-inhibitable cytochrome C reduction. Purified biosynthetic GM-CSF enhanced superoxide anion production by neutrophils in response to f-MLP, C5a desArg, and LTB₄. In contrast to several other factors which prime neutrophils, GM-CSF did not prime for an enhanced oxidative response to phorbol myristate acetate (PMA). These results suggest that GM-CSF may be an endogenous regulator of neutrophil inflammatory responses induced by the major physiological chemoattractants.

PRODUCTS OF OXIDATIVE metabolism mediate neutrophil (PMN) inflammatory responses and play an important role in host defense.¹ Bacterial-derived *N*-formyl-methionyl-leucyl-phenylalanine (f-MLP), complement-derived C5a, and the 5-lipoxygenation product of arachidonic acid metabolism, leukotriene B₄ (LTB₄) are chemotactic factors for PMN that initiate PMN inflammatory responses by activating oxidative metabolism.²⁻⁵ Recent studies identified a T lymphocyte-derived granulocyte-macrophage colony-stimulating factor (GM-CSF) that primes PMN for enhanced oxidative metabolism in response to f-MLP.⁶⁻⁸ Superoxide anion production was increased three- to fourfold in response to f-MLP by PMN preincubated with purified biosynthetic GM-CSF. Purified GM-CSF alone did not stimulate superoxide anion production. Since C5a and LTB₄ are also chemotactic, it is of considerable interest to determine whether GM-CSF also primes PMN to enhance oxidative metabolism in response to the other major physiological PMN chemoattractants. In addition to GM-CSF, other substances prime PMN, including endotoxin, f-MLP, and a product of B lymphocytes.⁹⁻¹¹ It was also of interest to determine whether the mechanism for priming by GM-CSF was the same as for these other substances.

MATERIALS AND METHODS

Materials. Phorbol myristate acetate (PMA) (Consolidated Midland Corp, Brewster, NY) was dissolved in absolute ethanol, 0.05 mg/mL, aliquoted and stored at -70 °C until used at a final concentration of 0.05 µg/mL. Purified C5a desArg (Upjohn Diagnostics, Kalamazoo, MI) was used at a final concentration of 8 ng/mL. The purity of C5a desArg was confirmed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) of radioiodinated C5a desArg which was visualized by radioautography. LTB₄ (Calbiochem, La Jolla, CA) was used at a final concentration of 10⁻⁶ mol/L. f-MLP (Sigma Chemical Co, St. Louis) was dissolved in dimethyl sulfoxide and used at a final concentration of 10⁻⁸ mol/L.

Isolation of human PMN. PMN were isolated from heparinized peripheral blood of healthy subjects by Ficoll-Hypaque gradient centrifugation as previously described.^{12,13} Red blood cells (RBC) were removed by sedimentation in 6% dextran (High Fraction, J.T. Baker Chemical Co, Phillipsburg, NJ). Residual RBC were subjected to hypotonic lysis for 30 seconds. The resulting cell preparations containing 97% PMN were washed and resuspended in Hanks' balanced salt solution (HBSS) (without phenol red) containing 10% fetal calf serum (FCS).

GM-CSF. GM-CSF was purified from serum-free medium conditioned by COS monkey kidney cells transfected with the GM-CSF cDNA clone in the p91023(B) vector as described previously, using gel filtration and reverse phase high performance liquid chromatography (HPLC).^{6,8} Purification of GM-CSF to apparent homogeneity was confirmed by the presence of a single iodinated 22,000-dalton protein band by SDS-PAGE. The protein concentration was determined by amino acid analysis; the specific activity of the purified protein assayed on human bone marrow is approximately 2 × 10⁸ units per mg.¹⁴ Purified GM-CSF was shown to be free of measurable endotoxin by the Limulus amoebocyte lysate assay (Sigma Chemical Co, St. Louis). Purified biosynthetic GM-CSF was used at a concentration of 100 pmol/L to study its effect on PMN oxidative metabolism. Maximal stimulation of colony formation by bone marrow cells and KG-1 cells as well as enhancement of neutrophil oxidative metabolism in response to f-MLP is seen at approximately 100 pmol/L.¹⁵

Assay for superoxide anion. PMN (5 × 10⁶/mL) were suspended in HBSS (without phenol red) containing 10% FCS, and 0.4 mL aliquots containing 2 × 10⁶ cells were incubated for two hours at 37 °C with 0.04 mL of protein diluent (negative control) or GM-CSF. After incubation, PMN were equally divided (1 × 10⁶ PMN/tube) and 0.010 mL of superoxide dismutase was added to one tube at a final concentration of 0.02 mg/mL. C5a or LTB₄ were

Table 1. Effect of Purified Recombinant GM-CSF on PMN Oxidative Metabolism

Oxidative Stimulus	Incubation Mixture	No. of Exps	Duration of Experiment (min)	Total Superoxide Anion Produced (nmol)*
f-MLP	diluent	4	4	6.0 ± 0.4
	GM-CSF	4	4	16.0 ± 0.4
C5a desArg	diluent	4	1	1.7 ± 0.1
	GM-CSF	4	1	3.2 ± 0.4
LTB ₄	diluent	4	1	2.4 ± 0.4
	GM-CSF	4	1	4.4 ± 0.4
PMA	diluent	4	25	74.4 ± 3.0
	GM-CSF	4	25	76.8 ± 1.0

*Mean response ± SEM of 10⁶ PMN.

added to each tube, thoroughly mixed, followed by the addition of 1 mL of cytochrome C (1.2 mg/mL in HBSS with 10% FCS). The cell suspensions were transferred to disposable 1-mL cuvettes, and superoxide dismutase-inhibitable cytochrome C reduction was measured spectrophotometrically at 550 nm for one minute at 37 °C with a Varian DMS 90 dual-beam spectrophotometer. Absorbance was recorded continuously with a strip-chart recorder and also at five-second intervals with a computer-assisted program. Superoxide anion production (nmoles) was calculated from reduced cytochrome C using an extinction coefficient of 21,100 mol/L⁻¹ cm⁻¹ and expressed as the mean determination of multiple experiments ± SEM.¹⁶ The effect of GM-CSF on oxidative metabolism of PMN in response to PMA and f-MLP was determined by incubating 2 × 10⁶ PMN with control and test preparations as above, adding 2 mL of cytochrome C, and then equally dividing the cell suspension into separate tubes. Superoxide dismutase was added to one tube, and PMA or f-MLP was added to both tubes. The cells were mixed and immediately transferred to cuvettes where the formation of reduced cytochrome C was monitored for four minutes (f-MLP) or 25 minutes (PMA). The data were recorded and the results calculated as described above.

RESULTS

Effect of purified biosynthetic GM-CSF on superoxide anion production by PMN in response to f-MLP. In preliminary experiments, a dose-response curve was established for f-MLP, and maximum production of superoxide anion occurred at a concentration of 10⁻⁸ mol/L f-MLP. Total superoxide anion produced over four minutes by 10⁶ PMN

**Fig 1. Effect of purified biosynthetic GM-CSF on superoxide anion production by PMN in response to f-MLP.****Fig 2. Effect of purified biosynthetic GM-CSF on superoxide anion production by PMN in response to C5a desArg.**

incubated with the protein diluent (negative control) was 6.0 ± 0.4 nmoles in response to 10⁻⁸ mol/L f-MLP (mean response of four experiments). Maximum priming by GM-CSF for oxidative metabolism was shown to occur at two hours.⁷ PMN preincubated for two hours with purified recombinant GM-CSF and then stimulated with f-MLP produced an average of 16.0 ± 0.4 nmoles superoxide anion (mean response of four experiments) (Table 1). A representative example of one experiment is shown in Fig 1. Enhancement of a maximal f-MLP response indicates a total increase in PMN oxidative metabolism and excludes measuring a shift in the f-MLP dose-response curve. The purified preparation of GM-CSF was free of measurable endotoxin (<0.1 ng/mL).

Effect of purified biosynthetic GM-CSF on superoxide anion production by PMN in response to C5a desArg. C5a desArg stimulated the production of 1.7 ± 0.1 nmoles superoxide anion over one minute (mean response of four experiments). PMN preincubated with GM-CSF, however, produced 3.2 ± 0.4 nmoles superoxide anion over the same period of time (mean response of four experiments) (Table 1). A representative experiment is shown in Fig 2.

Effect of purified biosynthetic GM-CSF on superoxide anion production in response to LTB₄. Maximum stimulation of oxidative metabolism of PMN in response to LTB₄ occurred at a concentration of 10⁻⁶ mol/L. At this concentration, LTB₄ stimulated the production of 2.4 ± 0.4 nmoles of superoxide anion by 10⁶ PMN over one minute (mean response of four experiments). Preincubation of PMN with GM-CSF for two hours followed by LTB₄ increased superoxide anion production to 4.4 ± 0.4 nmoles (mean response of four experiments) (Table 1). A representative experiment is shown in Fig 3.

Effect of purified biosynthetic GM-CSF on superoxide anion production in response to PMA. The specificity of PMN priming by GM-CSF was examined by measuring the effect of GM-CSF on PMN oxidative metabolism in

**Fig 3. Effect of purified biosynthetic GM-CSF on superoxide anion production by PMN in response to LTB₄.**

response to PMA. In the absence of GM-CSF, 10^6 PMN produced 74.4 ± 3.0 nmoles superoxide anion over 25 minutes which represents the entire course of PMA-induced activation (mean response of four experiments). After preincubating PMN with GM-CSF, the total response was unchanged with 76.8 ± 1.0 nmoles superoxide anion produced (mean response of four experiments) (Table 1). There was also no change in the rate of superoxide anion production. A representative example is shown in Fig 4.

DISCUSSION

PMN are chemoattracted to sites of inflammation where they serve as cytotoxic effector cells. Oxidative metabolism in PMNs is activated by physiological chemoattractants such as bacterial-related f-MLP, serum complement-derived C5a, and the 5-lipoxygenation product of arachidonic acid metabolism, LTB₄, with the production of toxic free radicals of oxygen.²⁻⁵ Products of oxidative metabolism provide one mechanism whereby PMN are cytotoxic.

Lymphokines have been described as endogenous regulators of oxidative metabolism in human monocytes,¹⁷ and colony-stimulating factors have been shown to potentiate granulocyte-mediated cellular cytotoxicity in the murine system.^{18,19} A potential physiological regulator of PMN oxidative metabolism was recently identified as the T cell-derived lymphokine, GM-CSF. GM-CSF, a 22,000-dalton glycoprotein, was shown to enhance the production of superoxide anion by PMN in response to f-MLP.⁷ The present studies were designed to determine whether GM-CSF also regulated PMN oxidative metabolism in response to other physiological chemoattractants.

Our results showed that PMN preincubated with biosynthetic purified GM-CSF enhanced superoxide anion production in response to purified C5a desArg and LTB₄ as well as f-MLP. Each chemoattractant was used at an optimum dose for stimulating superoxide anion production, so enhancement represented an increase in total response and not a shift in the dose-response curve. In contrast to GM-CSF priming for chemoattractants, GM-CSF did not enhance oxidative metabolism in response to PMA. There was no effect on the rate of superoxide anion production or the total amount of superoxide anion produced by PMN during the entire course of PMA activation.

Recently, endotoxin was shown to prime PMN for enhanced oxidative responses to f-MLP.¹⁰ Moreover, the time course for priming was similar to that obtained with GM-CSF. Several observations, however, exclude the possi-

bility that our results were due to the presence of endotoxin. First, HPLC-purified biosynthetic GM-CSF was compared to the HPLC diluent and to the other HPLC fractions that would contain the same contaminants. In addition, endotoxin was not detected by the Limulus amoebocyte assay in HPLC fractions containing neutrophil-activating activity, although the Limulus assay is sensitive enough to detect quantities of endotoxin considerably smaller than those required to prime PMN for enhanced oxidative metabolism.¹⁰ Finally, endotoxin and GM-CSF are different with respect to priming PMN in response to PMA. Endotoxin primes PMN for enhanced oxidative metabolism in response to PMA, whereas GM-CSF does not.

Lipoxygenase products also enhance neutrophil oxidative metabolism in response to f-MLP, but their effect of PMA responses has not been examined.²⁰ It will be of interest to compare the mechanism of action of these products with GM-CSF since these products could be responsible for the GM-CSF effect.

Other substances have also been shown to prime PMN for enhanced oxidative metabolism. In addition to endotoxin, priming has been shown to occur in response to subthreshold concentrations of f-MLP.^{9,21} Moreover, priming occurs in response to a factor present in the supernatant of a B lymphoblast cell line.¹¹ In contrast to GM-CSF, however, f-MLP, the B cell-derived factor, and endotoxin all prime PMN for enhanced oxidative metabolism in response to PMA.^{9,11,22,23} This finding suggests multiple mechanisms for priming with some specificity in the mechanism for PMN priming by GM-CSF. Although the mechanism for PMN priming by GM-CSF is unknown, a variety of secretory stimuli have been shown to increase f-MLP receptor availability by mobilizing an intracellular pool of f-MLP receptors.¹⁶ Moreover, recent studies show that short (15-minute) incubations of GM-CSF with neutrophils resulted in increased expression of high-affinity f-MLP receptors corresponding with enhanced chemotaxis in response to f-MLP, whereas more prolonged incubation of neutrophils with GM-CSF (two hours) resulted in the development of low-affinity receptors corresponding with enhanced oxidative metabolism in response to f-MLP.²⁴

PMN oxidative metabolism provides a mechanism for host defense through the production of potent derivatives of oxygen with microbicidal and tumoricidal activity. PMN oxidative metabolism requires precise regulation and control, as products of oxidative metabolism may induce tissue injury as well. GM-CSF may be an endogenous regulator of PMN oxidative metabolism and contribute to host defense-related reactions. In addition, GM-CSF could play a role in the pathophysiology of tissue injury associated with excessive inflammation as occurs in autoimmune diseases. GM-CSF regulation of PMN oxidative metabolism in response to different physiological chemoattractants may provide a common basis for understanding diverse biological functions of GM-CSF.

ACKNOWLEDGMENT

Activation of Plasminogen by Single-Chain Urokinase or by Two-Chain Urokinase—A Demonstration That Single-Chain Urokinase Has a Low Catalytic Activity (Pro-Urokinase)

By Ralph Pannell and Victor Gurewich

Single-chain urokinase (SC-UK) has an intrinsic amidolytic activity, as measured with synthetic substrate (Kabi S-2444; pyro-Glu-Gly-Arg-pNitroanilide), which was found to be 0.1% to 0.2% that of its plasmin-activated derivative, two-chain UK (TC-UK). A study of the reaction of SC-UK with plasminogen is complicated by the effect of the reaction product, plasmin, on both reactants. The resultant generation of TC-UK and Lys-plasminogen produces secondary reactions which greatly augment plasminogen activation. To confine enzymatic activity to the primary reaction, after pretreatment to eliminate trace TC-UK contaminants, SC-UK was incubated with Glu- or Lys-plasminogen in the presence of aprotinin (500 KIU/mL) to inhibit generated plasmin and dansyl-glutamyl-glycyl-argi-

nyl-chloromethylketone (20 μ mol/L), which irreversibly inhibited TC-UK but not SC-UK. Analysis by reducing sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) showed a plasminogen-activating activity for SC-UK that was ~0.4% that of TC-UK. Both SC-UK and TC-UK preferentially activated Lys-plasminogen over Glu-plasminogen. Similarly, Glu-plasminogen activation was augmented by lysine or soluble fibrin. The ratio of the reaction rates of SC-UK and TC-UK were comparable for Glu- and Lys-plasminogen. It is concluded that there is a major difference in the catalytic activities of SC-UK and TC-UK against plasminogen that is comparable to that against synthetic substrate.

© 1987 by Grune & Stratton, Inc.

SINGLE-CHAIN, high-mol-wt urokinase (SC-UK) was originally discovered in urine¹⁻³ and has been subsequently purified from the secretions of certain cells in culture^{4,5} and from blood plasma.⁶ This protein has been shown to be a natural precursor of two-chain, high-mol-wt urokinase (TC-UK) and to possess properties characteristic of a proenzyme or zymogen and has thus been referred to as pro-UK.^{4,7-9}

The relationship of SC-UK to TC-UK has obvious analogies within the single-chain:two-chain/zymogen:enzyme paradigm, which is well demonstrated within the serine protease class. Yet in the reaction of SC-UK with its physiological substrate, ie, Glu-plasminogen, its reactivity has been reported to be comparable to that of TC-UK,¹⁰ whereby it was concluded that the name pro-UK is inappropriate and a change in nomenclature to "single chain UK type plasminogen activator (scu-PA)" was recommended.¹¹ The analysis of the activity of SC-UK with plasminogen is complicated by the susceptibility of both reactants to enzymatic alteration by the primary reaction product (ie, Glu-plasmin). These side reactions, resulting in formation of TC-UK and Lys-plasminogen, greatly potentiate plasmin generation and interfere with the analysis of the primary reaction.

To dissect these reactions and to identify the component that is uniquely relevant to SC-UK, we exploited the wide differential between SC-UK and TC-UK in their susceptibilities to UK-reactive active site inhibitors such as diisopropylfluorophosphate (DFP)⁷ and dansyl-Glu-Gly-Arg-chloromethylketone (dns-GGA-ck) (vide infra). The plasmin-mediated side reactions were quenched by a competitive inhibitor, aprotinin, precluding the use of an enzymatic assay. We therefore used electrophoretic analysis of the reaction products. Although this method is not amenable to quantitation sufficient to allow derivation of kinetic parameters, it offers evidence that there is a major differential of net catalysis between SC-UK and TC-UK, which is of a similar quantitative order as has been observed with the synthetic substrate.

MATERIALS AND METHODS

Materials. Single-chain UK (>99% single chain; mol wt 55,000), purified from the culture medium of a human kidney tumor cell line, was provided by Collaborative Research (Lexington, MA). Two-chain UK (mol wt 55,000) was a product of Green Cross (Osaka, Japan). The WHO International Reference Preparation of UK, 66/46 (IRP-UK) was used as the activity standard (obtained from the National Institute for Biological Standards and Control, London). Amidolytic substrate (S-2444) was obtained from Kabi Vitrum (Stockholm, Sweden), aprotinin from FBA Pharmaceuticals (New York), dns-GGA-ck from Calbiochem (San Diego), DFP from Sigma Chemicals (St Louis), and "soluble" fibrin (Desafib) from American Diagnostica (Greenwich, CT).

Glu-plasminogen was purified from DFP-treated fresh plasma essentially by the method of Castellino and Powell.¹² Lys-plasminogen was prepared from purified Glu-plasminogen by the method of Lucas and co-workers.¹³ Plasmin was prepared by activation of plasminogen (2.5 μ mol/L) at pH 8.8 with either an equal volume of a 10% suspension of immobilized UK (Affi-Gel 15; Bio Rad, Richmond, CA) or an equal volume of Streptokinase (10,000 IU/mL) for 30 minutes at 37 °C.

Amidolytic activity of SC-UK or TC-UK. Amidolytic activity was measured with Kabi substrate S-2444 (pyro-Glu-Gly-Arg-pNitroanilide) (0.75 mmol/L) at 37 °C. The reaction buffer was 0.1 mol/L of Tris-HCl (pH 8.8), 0.1 mol/L of NaCl, and 0.1 mg/mL of bovine serum albumin (BSA). One enzyme unit (EU) was defined as

the amount of enzyme producing a change in absorbance (405 nmol) of 1 absorbance unit each minute. When assayed in this system, the IRP-UK had an activity of 275 EU/100,000 IU.

The activity of SC-UK was expressed in latent international units per milliliter representing the activity after plasmin activation. Activation of SC-UK to TC-UK was accomplished by incubation with an equal volume of plasmin (0.25 μ mol/L) for 30 to 45 minutes (37 °C). The amidolytic assay of the resultant TC-UK was performed in the presence of aprotinin (25 to 50 KIU/mL) to eliminate further plasmin action. The activated form of SC-UK was found to be comparable to TC-UK (~275 EU/mg).

SDS-PAGE. SDS-PAGE was performed by the method of Laemmli¹⁴ using a 10% polyacrylamide gel. Samples were prepared with 10 mmol/L of dithiothreitol and stained with Coomassie-Brilliant Blue G.

DFP treatment. Single-chain UK and plasminogen were treated with 1 mmol/L of DFP in 0.1 mol/L of sodium phosphate (pH 7.2), and 0.1 mol/L of NaCl. Incubation was carried out on ice for 18 hours. Under these conditions, TC-UK was totally inactivated, but full recovery of the latent activity of SC-UK was obtained when assayed after decay of the DFP.⁷ For preparative use, the treated product was dialyzed against 10 mmol/L of sodium acetate (pH 4.8) and 0.15 mol/L of NaCl and stored frozen.

Stability of SC-UK to dns-GGA-ck. At a concentration of 20 μ mol/L of dns-GGA-ck, complete and irreversible inhibition of TC-UK was obtained within 30 minutes at 37 °C or at room temperature. To test the stability of SC-UK to this inhibitor, SC-UK (0.1 mg/mL) was incubated with 20 μ mol/L of dns-GGA-ck for 2 hours at 37 °C in 0.2 mol/L of HEPES (pH 7.4), 0.3 mol/L of NaCl, 0.1% Triton X-100 (Sigma, St Louis). The solution was then diluted to .025 mg/mL of SC-UK with a buffer of 0.2 mol/L of Tris (pH 8.8), 0.3 mol/L NaCl and 0.2 mg/mL of BSA, and was allowed to incubate further at room temperature for 16 hours. Under the latter condition, dns-GGA-ck has been found to decay completely. The treated SC-UK and a control sample treated without dns-GGA-ck were then activated with plasmin and assayed with S-2444.

Evaluation of the influence of hydrolyzed dns-GGA-ck on the intrinsic activity of SC-UK. To test the effect of the tripeptide of dns-GGA-ck as a potential competitive inhibitor independent of noncompetitive inhibition by the reactive species, a hydrolysis-inactivated sample of the inhibitor was prepared and assayed. Dns-GGA-ck was inactivated by hydrolysis by dilution in 0.1 mol/L of Tris (pH 8.8), 0.3 mol/L of NaCl, and 0.2 mg/mL of BSA, and storage at room temperature for 3 days. The resulting product was assayed as a potential competitive inhibitor against both TC-UK and the inherent activity of SC-UK, using the amidolytic assay. The substrate tripeptide is identical with the tripeptide of dns-GGA-ck. The substrate was at an assay concentration of 0.75 mmol/L; the hydrolyzed inhibitor was tested up to 50 μ mol/L. No significant inhibition was observed with either SC-UK or TC-UK.

Plasminogen degradation by SC-UK or TC-UK. Glu-plasminogen or Lys-plasminogen (0.23 mg/mL) and either SC-UK (5,000, 10,000, or 20,000 IU/mL) or TC-UK (5, 10, or 20 IU/mL) were incubated (37 °C) in a reaction medium comprising 0.2 mol/L of HEPES-HCl (pH 7.4), 0.3 mol/L of NaCl, 0.01% Triton X-100, and aprotinin (500 KIU/mL). SC-UK was pretreated with the dns-GGA-ck (80 μ mol/L at room temperature for 30 minutes in the reaction buffer) prior to dilution into the assay to eliminate residual TC-UK activity, and dns-GGA-ck (20 μ mol/L) was present in the reaction mixture for SC-UK (but not for TC-UK). At 1 and 2 hours, reactions were stopped by dilution of aliquots with SDS sample buffer (reducing).

To test the effect of occupancy of the lysine binding sites of Glu-plasminogen on its susceptibility to SC-UK, the reaction was

run as described above for 2 hours but with the addition of either 0.25 mg/mL of soluble fibrin or 25 mmol/L of lysine. A concentration of 5,000 IU/mL SC-UK or 25 IU/mL of TC-UK was used.

RESULTS

Effect of inhibitors on the amidolytic activities of SC-UK and TC-UK. Preparations of SC-UK were found to have a low but variable specific activity against the synthetic substrate S-2444 as expressed by the ratio of activities before and after plasmin treatment. The variability in this measurement could be attributed to even very small contamination with TC-UK. When preparations were pretreated with DFP (1 mmol/L), sufficient to abolish the activity of the contaminant, a more consistent result was obtained, which showed that SC-UK had an inhibitor resistant activity corresponding to 0.1% to 0.2% of its latent activity as previously observed.¹⁵

A similar result was obtained with the more specific inhibitor dns-GGA-ck. Treatment with 20 μ mol/L of dns-GGA-ck completely inactivated TC-UK, whereas after provision for decay of the inhibitor by hydrolysis (described in the Methods section), the plasmin activatable activity of SC-UK was at least 97% recoverable.

Effects of inhibitors on the reaction of SC-UK with plasminogen. In mixtures of SC-UK with plasminogen (whether Glu or Lys), there was rapid activation of the plasminogen and conversion of SC-UK to the two chains of TC-UK, indicating that TC-UK was being generated and possibly was dominating the reaction. When aprotinin (100 KIU/mL) and dns-GGA-ck (20 μ mol/L) were included in the reaction mixture, the activation of plasminogen was greatly decreased even though electrophoretic analysis revealed that significant traces of SC-UK were still being converted to TC-UK. When the concentration of aprotinin was increased to 500 KIU/mL, however, the secondary reaction of SC-UK activation appeared to be prevented.

Comparison of the activation of Glu-plasminogen by SC-UK and TC-UK. Under these conditions limiting the secondary reactions, the activity of SC-UK was quantitatively compared with that of TC-UK. With both forms of UK, there was a concentration- and time-dependent generation of the heavy (mol wt 67,000) and light (mol wt 25,000) chains of plasmin (Figs 1A and B). Densitometric scanning of the gels showed that the plasmin produced by 10,000 IU/mL of SC-UK in 1 hour was approximately equal to that which occurred with 20 IU/mL of UK in 2 hours. Thus, a ratio of ~250 was calculated, ie, SC-UK was 0.4% as active as TC-UK against plasminogen. This ratio was comparable to its activity against synthetic substrate (0.1% to 0.2%).

Comparison of the activations of Lys-plasminogen and Glu-plasminogen. When Lys-plasminogen was substituted for Glu-plasminogen in the above reaction mixtures, the rate of conversion by both activators was increased, as shown in Figs 2A and B, representing 1 and 2 hours of incubation, respectively. A similar differential between the activities of TC-UK and SC-UK was seen with Lys- as with Glu-plasminogen (5,000 IU/mL of SC-UK $\times$ 1 hour was comparable to 10 IU/mL of TC-UK $\times$ 2 hours, or a ratio of ~250).

Fig 1. (A) Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions of mixtures of Glu-plasminogen, aprotinin (500 KIU/mL), dns-GGA-cK, and activators incubated (37 °C) for 1 hour. Left: (a) two-chain urokinase (TC-UK) plus single-chain urokinase (SC-UK) marker; TC-UK at (1) 5, (2) 10, and (3) 20 IU/mL. Right: SC-UK at (4) 5,000, (5) 10,000, and (6) 20,000 IU/mL; (b) Glu-plasminogen marker. The heavy and light chains of Glu-plasmin appear at mol wts 67,000 and 25,000, respectively. (B) SDS-PAGE of the mixtures shown in A after 2-hour incubation.

Effect of lysine and of soluble fibrin on Glu-plasminogen activation. When lysine or soluble fibrin was used as a modifier of Glu-plasminogen, the observed increased susceptibility of Lys-plasminogen to activation was found to extend to this conformationally modified form. Quantitation by densitometric scanning of the gel shown in Fig 3 showed that whereas 5,000 IU/mL of SC-UK activated <15% of Glu-plasminogen in 2 hours, the inclusion of 25 mmol/L of lysine enhanced activation to ~45%. Soluble fibrin at 0.25 mg/mL gave a significant but smaller enhancement to ~30% conversion.

DISCUSSION

When plasminogen activation was measured under conditions designed to isolate the reaction inherent to SC-UK, a consistent magnitude of discrepancy was observed between SC-UK and TC-UK in their abilities to activate either Glu-plasminogen or Lys-plasminogen. The activity of SC-UK was ~0.4% that of TC-UK, a differential comparable to their respective rates of hydrolysis of synthetic substrate S-2444. These findings are compatible with other zymogenic characteristics of SC-UK, such as its relative resistance to

Fig 2. (A) Reduced sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of mixtures of Lys-plasminogen, aprotinin (500 KIU/mL), dns-GGA-cK and two-chain urokinase (TC-UK) at (1) 5, (2) 10, and (3) 20 IU/mL and single-chain urokinase (SC-UK) at (4) 5,000, (5) 10,000, and (6) 20,000 IU/mL incubated (37 °C) for 1 hour; (a) TC-UK plus SC-UK marker; (b) Lys-plasminogen marker. Reduced sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of mixtures of Glu-plasminogen incubated (37 °C) for 2 hours with single-chain urokinase (SC-UK) (5,000 IU/mL) (1) alone, (2) plus lysine, and (3) plus soluble fibrin; or two-chain urokinase (TC-UK) (25 IU/mL) (1) alone, (2) plus lysine, and (3) plus soluble fibrin; (a) soluble fibrin marker. In lanes 2 and 3, the appearance of the heavy and light chains of plasmin are seen at mol wts 67,000 and 25,000, respectively.

inhibitors like DFP or dns-GGA-ck, and its stability in plasma.⁸

The observance of such a differential between the reactivities of TC-UK and of SC-UK with the physiological substrate, Glu-plasminogen, is at variance, however, with the report of Collen and colleagues¹⁰ in which the activity of SC-UK was stated to have a catalytic efficiency comparable to that of TC-UK. The discrepancy must be evaluated in terms of the methods of analysis used and particularly the measures taken to eliminate side reactions, principally the generation of TC-UK. These authors used the competitive influence of the synthetic plasmin substrate itself (S2251 at 1 mmol/L) to inhibit the action of plasmin on SC-UK at a concentration that is four times the K_m but that occupies plasmin only to the extent of 80% of its V_{max} (calculated from Michaelis-Menten equation). Therefore, plasmin inhibition may not have been complete. Moreover, the product of this substrate, bearing a carboxy-terminal lysine residue, has the potential to modify Glu-plasminogen by occupying the lysine binding site which promotes its activatability either by UK¹⁶

or by pro-UK (Fig 3). Ultimately, the confirmation of one view or the other must await the application of additional experimental approaches to the problem of isolating the primary reaction.

Evidence for a low inherent activity of SC-UK has also been observed in other systems. Preparations free of TC-UK contamination induce fibrinolysis on a standard fibrin plate and in a model plasma clot lysis system.^{7,8} We have proposed that this inherent activity of SC-UK may constitute a trigger that leads to plasmin generation on the clot surface primarily by way of the positive feedback of the secondary reaction of TC-UK production.^{7,17} The side reaction that is triggered by plasmin activation of SC-UK, posing methodologic complications, probably serves as a useful physiologic amplifier, greatly increasing the rate of localized plasmin generation.

Although the intrinsic activity of the SC-UK is not incompatible with its proenzyme designation,¹⁸ the magnitude of this activity is relatively large. Therefore, SC-UK may be seen as occurring somewhere along a spectrum defined by an absolutely inactive zymogen at one extreme and the fully activated enzymatic form, here represented by TC-UK, at the other extreme. The appropriate place for SC-UK along this spectrum has been defined here only in qualitative terms. Quantitative appraisal of that position has been thwarted by the methodologic problems of measuring the kinetics of the primary reaction of SC-UK and Glu-plasminogen in functional isolation.

With Lys-plasminogen as substrate, plasmin generation was significantly more rapid with either activator, although the ratio of their reaction rates remained comparable. Similarly, a potentiation of plasmin generation occurred when lysine or soluble fibrin was added to Glu-plasminogen reaction mixtures. This effect of lysine or soluble fibrin is related to the conformational change induced in Glu-plasminogen by occupancy of the fibrin/lysine binding site(s).¹⁹ We recently proposed that the preferential activation of fibrin-bound plasminogen is an important element of the mechanism responsible for the fibrin specificity of SC-UK.¹⁵ A preferential activation of Lys-plasminogen over Glu-plasminogen has previously been reported for TC-UK.¹⁹

In conclusion, under conditions in which the primary reaction inherent to SC-UK was isolated and compared with that of TC-UK, a major difference was consistently observed between their respective activities, whether as hydrolysis of the synthetic substrate S-2444, reaction with inhibitors such as DFP or dns-GGA-ck, or proteolytic activation of either Glu-plasminogen or Lys-plasminogen.

Topology and Order of Formation of Interchain Disulfide Bonds in von Willebrand Factor

By Denisa D. Wagner, Sarah O. Lawrence, Betsy M. Ohlsson-Wilhelm, Philip J. Fay, and Victor J. Marder

Interchain disulfide bonds between the subunits in von Willebrand factor (vWf) dimers and in vWf multimers have been studied using some unique features of the cultured human umbilical vein endothelial cell system. Ammonium chloride inhibition of multimerization of vWf allowed selective examination of vWf dimeric molecules, and monoclonal antibody against the vWf propolypeptide was used to separate pro-vWf dimers from mature dimers. After cleavage of dimers and multimers with *Staphylococcus aureus* V-8 protease, the location of interchain disulfide bonds in amino (N)-terminal or carboxyl (C)-terminal frag-

ments was determined by gel electrophoresis under reduced and nonreduced conditions. The first interchain disulfide bonds formed during dimerization are in the C-terminal region of the subunits, whereas interdimer disulfide bonds are located in the N-terminal portion. These data confirm recent electron microscopic projections of disulfide bond locations and provide support to the hypothetical role of the propolypeptide in the multimerization process.

© 1987 by Grune & Stratton, Inc.

THE LARGEST von Willebrand factor (vWf) multimers are the most active in in vitro platelet aggregation and binding assays, and their absence in vivo results in type IIA von Willebrand disease (vWd).¹ Therefore, the formation of the interchain disulfide bonds is a crucial aspect of vWf biosynthesis. Studies using cultured endothelial cells indicate that dimers of pro-vWf subunits are formed in the endoplasmic reticulum, and only after these are transported to the Golgi apparatus does interdimer disulfide bond formation begin.² This latter process is pH sensitive because it is inhibited in the presence of a weak base such as ammonium chloride.³ Simultaneous with multimerization, the vWf propolypeptide (von Willebrand antigen II),⁴ located at the N-terminal end of the vWf subunit,⁵⁻⁷ is proteolytically removed,^{8,9} and vWf is secreted into the culture medium or stored in the Weibel-Palade bodies.¹⁰

Many multimeric sizes of vWf are found in plasma.¹ The smallest circulating species is a dimer^{11,12} that could correspond to the dimeric molecule formed in the endoplasmic reticulum. Limited proteolysis of plasma vWf with *Staphylococcus aureus* V-8 protease produces a single cleavage in the vWf subunit, yielding two large homodimers,^{13,14} indicating that multimerization occurs in a head-to-head and tail-to-tail fashion. Electron microscopic observations confirm this type of arrangement and in addition reveal the vWf multimers to be elongated molecules with the interchain disulfide bonds located near the N-terminals and C-terminals of the subunits.^{12,15} In this study, we examine which of these interchain disulfide bonds is formed first (ie, in the endoplasmic reticulum) during dimerization of vWf and compare our result to a preliminary electron microscopic observation which assigns the interchain link of the smallest circulating species as being between the C-terminal regions of the vWf subunits.¹⁶

MATERIALS AND METHODS

Cells and culture conditions. Endothelial cells were obtained from human umbilical vein by mild proteolytic digestion as described previously^{10,17}; only primary cultures were used. Cells were cultured in McCoy's 5A medium (Flow Laboratories, Inc, McLean, VA) containing 20% fetal bovine serum (FBS). Ammonium chloride (Fischer Scientific, Rochester, NY) was dissolved in culture medium. For metabolic labeling, cells were grown for 3 days in the presence of [³⁵S]methionine (25 μ Ci/mL, 1148 Ci/mmol) (New England Nuclear, Billerica, MA).

Antibodies. Anti-vWf antiserum was purchased from Calbiochem-Behring (San Diego). Antiserum against human pro-vWf was prepared by immunization of New Zealand albino rabbits with purified von Willebrand antigen II (vW AgII) and vWf. Antiserum was rendered monospecific for pro-vWf by filtration through Sepharose CL-4B coupled with plasma from a patient with severe vWd. This polyclonal antiserum recognizes both the vWf propolypeptide (vW AgII) and the mature vWf multimers. Monoclonal antibodies against the 100-kd propolypeptide of vWf¹⁸ were prepared as follows: Spleen cells from female BALB/c mice hyperimmunized with the propolypeptide were fused to the myeloma cell line P3X63Ag8.653¹⁸ at a ratio of 3:1, using standard techniques with HAT selection.¹⁹ Supernatants from each resulting clone were tested by enzyme-linked immunosorbent assay (ELISA) against the propolypeptide, mature vWf, and fibronectin. Antibody-producing clones with preferential activity against the 100-kd propolypeptide of vWf were expanded and recloned until clonal homogeneity was achieved (two to three subclonings). These were then frozen and stored. The specificity of antibody produced by such clones was confirmed by Western blotting.²⁰

Purification of vWf. vWf was immunopurified as described previously.² For purification of molecules containing the propolypeptide, 300 μ L of supernatant containing monoclonal antibody was used for each sample.

***S aureus* V-8 cleavage.** Purified vWf in electrophoresis sample buffer containing 2% sodium dodecyl sulfate (SDS)²¹ was diluted twofold in water containing *S aureus* V-8 protease so that the final concentration of the enzyme was 10 μ g/mL. After 10-minute digestion at room temperature, the reaction was stopped by adding 1/10 vol of 20% SDS and boiling. Samples were immediately prepared for electrophoresis with or without dithiothreitol.

Electrophoresis gels. Agarose horizontal slab gels were prepared using a solution of 2% agarose, 0.1% SDS in 0.05 mol/L of phosphate buffer at pH 7.0, and running buffer was 0.1 mol/L of phosphate buffer, pH 7.0, with 0.1% SDS. SDS polyacrylamide gels were prepared as described by Laemmli.²¹ For two-dimensional gel electrophoresis, protein was first run nonreduced on a 5% polyacrylamide gel. The strip was cut out and incubated with constant shaking for 20 minutes at room temperature in running buffer²¹ that contained 50 mmol/L of dithiothreitol. The strip was then transferred to the top of an identical 5% SDS polyacrylamide gel and overlaid with 0.5% agarose and 0.1 mol/L of dithiothreitol in running buffer before electrophoresis. Western blotting analysis was performed as previously described.²² The primary antibody solution consisted of a mixture of three different anti-vWf propolypeptide monoclonal antibody supernatants each diluted 1:25.

RESULTS

Ammonium chloride inhibits interdimer disulfide bond formation and partially blocks cleavage of prosequence.³ Therefore, in its presence, endothelial cells in culture secrete dimeric molecules, some of which contain pro-vWf subunits (Fig 1). *S aureus* V-8 protease cleaves the vWf or pro-vWf subunit in two fragments (refs. 13 and 14 and our preliminary results). As diagrammed schematically in Fig 1, the C-terminal fragments released from the two types of subunit would have to be identical, whereas the N-terminal fragment from the pro-vWf subunit should be larger, because it contains in addition the 100-kD prosequence. To localize the interchain disulfide bond(s) in the dimers to the N-terminal or C-terminal portion of the molecule (options A or B, Fig 1), we generated these V-8 protease fragments and determined which were dimeric in the absence of reduction.

Human umbilical vein endothelial cells were metabolically labeled in the presence of 25 mmol/L of ammonium chloride. Culture medium was collected, and molecules containing the pro-vWf sequence were purified by the use of monoclonal antibody prepared against the propolypeptide. vWf molecules containing mature subunits were then isolated from the supernatant with a polyclonal anti-vWf antiserum. The purified protein was examined nonreduced on a 2% agarose gel (Fig 2A), and both reduced and nonreduced protein was examined on a 5% polyacrylamide gel (Fig 2B). The sample purified with the antipropolypeptide monoclonal antibody contained mostly dimers of pro-vWf subunits and free propolypeptide.⁴ The protein purified with the polyclonal antiserum was composed predominantly of dimers of mature

subunits and did not contain the free propolypeptide (Fig 2). Two major bands were produced by V-8 protease cleavage of the mature vWf and pro-vWf dimers. One band was shared between the two samples (Fig 2B, lanes 2 and 4 reduced, lanes 6 and 8 nonreduced) and therefore represents the C-terminal fragment (CTF). As expected, the other N-terminal cleavage fragment was larger when obtained from the pro-vWf dimer (pro-NTF) than from mature vWf dimers (NTF) (Fig 2b). The identification of the fragments was further confirmed by Western blotting as follows: a mixture of pro-vWf and vWf dimers purified from culture medium of ammonium chloride-treated cells by polyclonal antiserum against pro-vWf were digested by V-8 protease. The starting material and the resulting fragments were electrophoresed on a reduced 6% polyacrylamide gel. Western blots of this gel with a mixture of antipropolypeptide monoclonal antibodies (Fig 3) identified the pro-vWf subunit, the propolypeptide, and the pro-NTF, and demonstrated that the large pro-NTF indeed contains the N-terminal portion of the molecule.

Both pro-NTF and NTF migrated faster on gels nonreduced, indicative of the presence of intrachain disulfide bonds (Fig 2B). On the other hand, the C-terminal fragment migrated significantly more slowly nonreduced, suggesting that it was dimeric. To show this more convincingly, the *S aureus* V-8 proteolytic fragments were examined by two-dimensional gel electrophoresis (Fig 4). In the first dimension, the samples were electrophoresed nonreduced on a 5% polyacrylamide gel; then the lanes were cut out, incubated in the presence of a reducing agent, and placed on top of a second 5% polyacrylamide gel (as shown in Fig 4) and electrophoresed. Only CTF migrated well below the diagonal of the gel, confirming that it was dimeric prior to reduction. It appears therefore that the dimers that are the building blocks of vWf polymers^{2,23} are held together by disulfide bond(s) localized in the C-terminal region of the polypeptide chain (option B, Fig 1).

The major products of *S aureus* V-8 cleavage of plasma vWf are two large distinct dimeric fragments,^{13,14} indicating that both ends of the vWf subunit form interchain disulfide bonds. Because the first link between the subunits of dimers is in the C-terminal region, the interdimer disulfides formed later in the processing of vWF² should involve the other (N-terminal) end of the subunit. If this is so, the amount of the monomeric N-terminal fragment should decrease with an increase in size of vWf multimers submitted to *S aureus*

Fig 1. Schematic representation of the location of disulfide bonds in the pro-vWf dimer and mature vWf dimer. The arrowheads indicate the approximate cleavage site for *Staphylococcus aureus* V-8 protease. Following cleavage, V-8 protease produces N-terminal fragments (pro-NTF and NTF) and C-terminal fragments (CTF). If the interchain disulfide bond(s) of the dimers is located at the N-terminal part of the molecule (option A), the pro-NTF and NTF will be dimeric, whereas a location of the disulfide bond(s) at the C-terminal end (option B) will produce dimeric CTF.

Fig 2. *Staphylococcus aureus* V-8 cleavage of pro-vWf and vWf dimers. (A) The wide range in size of vWf multimers secreted constitutively by metabolically labeled endothelial cell cultures is indicated in lane 1. In the presence of 25 mmol/L of ammonium chloride, only vWf dimers are produced, and these can be separated immunologically (described in text) into pro-vWf dimers (lane 2) and mature vWf dimers (lane 3). Purification of the pro-vWf dimer with specific monoclonal antibody against the prosequence also precipitates free propolypeptide. Autoradiograph of a 2% agarose gel is shown. (B) Autoradiograph of a 5% polyacrylamide gel, the left portion of which (lanes 1 through 4) was obtained with reduced protein. Pro-vWf dimers were examined before V-8 protease cleavage (lanes 1 and 5) and after cleavage (lanes 2 and 6). Mature vWf dimers are similarly shown before protease cleavage (lanes 3 and 7) and after cleavage (lanes 4 and 8). The 100-kd propolypeptide is not cleaved by the V-8 protease. Comparison of migration of the fragments with mol wt markers gives the following mol wts: pro-NTF 200 kd, CTF 145 kd, and NTF 125 kd. Because vWf and pro-vWf migrate anomalously in polyacrylamide gels,⁴ these estimated mol wts are likely incorrect. The minor band which migrates more rapidly than the pro-NTF and NTF fragments is a secondary cleavage product of these fragments. The small amount of mature vWf subunit in the pro-vWf preparation (lane 1) indicates that a minor fraction of the dimers synthesized in the presence of ammonium chloride are heterodimeric, that is, they contain both types of subunits. The small amount of pro-vWf subunit present in the vWf preparation (lane 3) reflects incomplete prior removal of all pro-vWf by the antipropolypeptide monoclonal antibody.

V-8 digestion. vWf purified from endothelial cell's culture medium (using anti-vWf antiserum) is predominantly composed of small vWf multimers²² (Fig 2a), whereas the protein stored in the endothelial cells is highly multimerized.²⁴ In the endothelial cell's endoplasmic reticulum, there is in addition a large pool of pro-vWf dimers that we can separate from the mature vWf with antipropolypeptide monoclonal antibodies. Metabolically labeled endothelial cell lysate was therefore subjected to a two-step purification procedure. The first step removed the prosequence containing molecules that were

discarded, and the second isolated the remaining high-mol-wt (HMW) vWf multimers, using a polyclonal anti-vWf antiserum. These large cellular multimers were subjected to *S. aureus* V-8 digestion in parallel with the predominantly small multimers purified from the culture medium. The starting material and the resulting fragments were analyzed nonreduced on 6% acrylamide gels (Fig 5). Significantly less monomeric N-terminal fragment was generated from the cellular sample (Fig 5, lane 4) than from the secreted vWf (Fig 5, lane 2), indicating that this portion of the subunit

Fig 3. Western blot of *Staphylococcus aureus* V-8 cleavage products with antipropolypeptide monoclonal antibodies. Culture medium from metabolically labeled cells in the presence of 25 mmol/L of ammonium chloride was purified with polyclonal anti-pro-vWf antiserum and electrophoresed reduced on a 6% polyacrylamide gel before (lane 1) and after (lane 2) digestion with V-8 protease. The Western blot of this gel was done with a mixture of three monoclonal antibodies directed against the propolypeptide. Only the pro-NTF, not the CTF and NTF, reacted positively with the antibodies. Indications at left show migration of markers: myosin, 200 kd; β -galactosidase, 130 kd; phosphorylase b, 92.5 kd.

became highly involved in interchain disulfide bonding. Two-dimensional gel electrophoresis of the digested samples (not shown) revealed that the slowly migrating doublet contains both the dimeric C-terminal fragment and the dimeric N-terminal fragment. Because the *S aureus* V-8 cleaves the vWf subunit close to its center, the dimers of the resulting fragments appear similar in size in our gel system. The doublet can be better resolved on low-percentage acrylamide gels in which the CTF dimer migrates slower than the

NTF dimer (not shown). The very small amount of monomeric N-terminal fragment (seen only after long autoradiographic exposures) produced from HMW vWf multimers confirms that this is the part of the subunit involved in the polymerization of the vWf dimers.

DISCUSSION

Although most of the amino acid sequence of the mature vWf subunit is known from molecular cloning studies⁵⁻⁷ and protein sequencing,²⁵ the exact number and location of the interchain disulfide bonds in the vWf multimers remains to be elucidated. To localize the interchain disulfide bonds in vWf multimers, the structure of the protein was first simplified to dimers. This was accomplished by culturing human umbilical vein endothelial cells in the presence of a weak base (ammonium chloride) that inhibits the intracellular multimerization of dimers.³ The resulting dimeric molecules were separated into two groups, namely, those containing pro-vWf subunits and those built of mature subunits. For this purpose, we used monoclonal antibodies prepared against the vWf propolypeptide. The two sets of dimers were submitted to cleavage with *S aureus* V-8 protease, and the resulting fragments were compared reduced and nonreduced and by two-dimensional gel electrophoresis. A shared C-terminal fragment was shown to be dimeric (Figs 2 and 4). Therefore, the first interchain disulfide bonds formed in the biosynthesis of vWf during dimerization are in this C-terminal region of the subunit.

We cannot reconcile why our results showed a C-terminal fragment that was larger than the N-terminal fragment whereas other researchers have reported opposite results following V-8 digestion of mature vWf.¹³ It is possible that the presence of SDS in our samples uncovered a different primary cleavage site for the protease, also localized in the center of the subunit, or that the fragments have different electrophoretic properties in our gel system. The sum of the apparent mol wts of the two fragments, ie, 145 plus 125 kd, corresponds to the size of vWf subunit (270 kd) determined

Fig 4. Two-dimensional gel electrophoresis of *Staphylococcus aureus* V-8 cleavage products (autoradiographs of 5% polyacrylamide gels). Samples were analyzed nonreduced in the first dimension as shown (left to right) and reduced in the second (top to bottom). Fragments were obtained from (A) pro-vWf dimers and (B) mature vWf dimers.

Fig 5. *Staphylococcus aureus* V-8 cleavage of multimeric vWf (autoradiograph of nonreduced 6% polyacrylamide gels). Lanes 1 and 2 show results obtained with constitutively secreted vWf obtained from long-term labeled human endothelial cell medium and lanes 3 and 4 show results with high-mol-wt (HMW) cellular vWf multimers. Lanes 1 and 3 represent the starting material, and lanes 2 and 4 show the cleavage products after V-8 protease digestion. Both CTF and NTF fragments obtained from the HMW multimers are dimeric, whereas the NTF obtained from culture medium vWf is mostly monomeric.

by amino acid sequence and carbohydrate content studies of the protein.²⁵ Both the N-terminal⁷ and C-terminal⁵⁻⁷ regions of the vWf polypeptide chain are rich in cysteines, but the center portion of the mature subunit contains a stretch of ~600 amino acids that is poor in cysteines,²⁶ similar to the disulfide distribution of fibronectin.²⁷ In addition, we showed that vWf dimers are similar to fibronectin dimers,^{28,29} in that both are held together at the C-terminal portion of the subunits (Fig 1, option B). In human cells, the formation of the vWf dimers is dependent on N-linked glycosylation of the subunits, since tunicamycin, which inhibits glycosylation, also blocks processing of vWf beyond the monomeric form.³

A recent abstract¹⁶ compared the electron microscopic appearance of N-terminal and C-terminal fragments of plasma vWf with that of the smallest circulating form of vWf and suggested that this dimeric molecule is held together in the C-terminal region of the subunits. It appears therefore that these small circulating species of vWf are not degradation products of large multimers but instead represent the dimeric molecules synthesized in the endoplasmic reticulum and secreted by endothelial cells^{2,23} and megakaryocytes³⁰ in culture.

Comparison of the nonreduced fragments obtained from dimeric and multimeric molecules (Figs 2 and 5) reveals that the interdimer disulfide bonds involve the N-terminal region of the subunit. This may occur by direct oxidation of the free sulfhydryl groups present on the pro vWf-dimers,² which are absent from mature vWf multimers.^{31,32} The multimerization process is likely to begin in the Trans Golgi apparatus³ and possibly continues during the packaging of the protein into the Weibel-Palade bodies. Loscalzo and colleagues showed that at high concentrations vWf can aggregate by noncovalent forces and proposed that such forces might be important during intracellular assembly of vWf.³³ We hypothesized that the large propolypeptide of vWf may assist in the proper alignment of the pro-vWf dimers for the interdimer disulfide bond formation.² The observation that these links are formed in proximity to the prosequence, ie, in the N-terminal region of the subunit, is further support for this hypothesis.

ACKNOWLEDGMENT

We thank Judith Enyeart for culturing the endothelial cells, Susan Malerk for technical assistance, and Carol Weed for typing the manuscript.

Regulation of Early Human Hematopoietic (BFU-E and CFU-GEMM) Progenitor Cells In Vitro by Interleukin 1-Induced Fibroblast-Conditioned Medium

By James R. Zucali, Hal E. Broxmeyer, Charles A. Dinarello, Mary Ann Gross, and Roy S. Weiner

Stimulators of human erythroid burst-forming units (BFU-E) and multipotential colony-forming cells (CFU-GEMM) can be produced by a number of different cell types. A product of human peripheral blood monocytes, interleukin 1 (IL-1), was evaluated for its ability to stimulate fibroblast cultures to produce stimulators of human bone marrow BFU-E and CFU-GEMM colony formation. BFU-E and CFU-GEMM colony formation was evaluated using low-density, nonadherent low-density, and T lymphocyte-depleted nonadherent low-density human bone marrow cells cultured in the presence of a source of pure human erythropoietin. Both human monocyte conditioned medium (MCM) and human recombinant IL-1 (hrIL-1) induced fibroblasts to

produce stimulators of BFU-E and CFU-GEMM in a dose-dependent fashion with maximal colony formation occurring when fibroblasts were stimulated by 25% MCM or 140 ng/mL ROO6B hrIL-1, or 1.25 to 5 ng/mL ROO6T hrIL-1. Preincubation of MCM and hrIL-1 with an antibody to IL-1 inactivated the ability of MCM and hrIL-1 to induce the release of erythroid and multipotential colony stimulating activity from fibroblasts. These results suggest that monocyte-derived IL-1 is involved in regulating the production of humoral stimulators of early human hematopoietic progenitors.

© 1987 by Grune & Stratton, Inc.

GROWTH OF HUMAN hematopoietic progenitor cells in clonal cultures requires the presence of specific soluble stimulating factors. Besides erythropoietin, erythroid burst-forming units (BFU-E) and multipotential (CFU-GEMM) progenitor cells require factors present in medium conditioned by blood leukocytes or other sources of burst promoting activity (BPA).^{1,2} A variety of cell types have been implicated in BPA production. These include monocytes and/or macrophages,^{3,4} T lymphocytes,^{5,6} and endothelial cells.⁷ Similar cell types have also been reported to be involved in GM-CSA production.⁸⁻¹⁰ Recent studies have focused on the monocyte as a central cell involved in the regulation of GM-CSA and BPA production.^{11,12} These studies report that monocytes produce a monokine or monokines which function by recruiting other accessory cells to produce GM-CSA and/or BPA.

We have recently identified interleukin 1 (IL-1) as one monocyte product which induces confluent fibroblast cultures to produce and release GM-CSA.¹³ Both purified human monocyte-derived IL-1 and human recombinant IL-1 (hrIL-1) reproduce the biologic activity found in this monocyte conditioned medium (MCM). In addition, a polyclonal antibody to IL-1 abolished this biologic activity. In the present study, we demonstrate that confluent fibroblast cultures, when stimulated by a factor present in MCM or by hrIL-1 also produce stimulators of colony formation by BFU-E and CFU-GEMM. Furthermore, the stimulation of fibroblast cultures by MCM or hrIL-1 can be blocked by the addition of antibody to IL-1.

MATERIALS AND METHODS

Isolation of peripheral blood monocytes. Peripheral blood cells were obtained from normal donors who had given informed consent. Peripheral blood leukocytes were isolated following semicontinuous flow pheresis¹⁴ and the buffy coat was diluted with two volumes of Hanks' balanced salt solution without calcium and magnesium prior to removing platelets by centrifugation at $150 \times g$ for ten minutes. This cell suspension was centrifuged over Ficoll-Hypaque (specific gravity 1.078) to remove contaminating granulocytes and erythrocytes. The mononuclear cells at the interface were collected and separated into two populations, monocytes and lymphocytes, by elutriation centrifugation as previously reported.^{13,15} Using this technique, monocytes were collected as a homogeneous cell population and further subjected to 2-aminoethylisothiuronium bromide

hydrobromide (AET)-treated sheep erythrocyte depletion to remove any contaminating T lymphocytes. Nonrosetting cells were separated by centrifugation through Ficoll-Hypaque. The purity of nonrosetting cells was determined using OKT3 (Ortho Diagnostics, Raritan, NJ) and LeuM3 (Becton Dickinson, Mountain View, CA) monoclonal antibodies and indirect immunofluorescence with affinity-purified goat antimouse IgG F(ab')₂-FITC (Cappel, West Chester, PA). The cells were analyzed using both fluorescence microscopy and a Coulter Model C flow cytometer. Background staining was determined on cells treated with nonimmune mouse immunoglobulins and second antibody. In addition, monocytes were identified on cytocentrifuge-prepared slides stained with Wright's-Giemsa and nonspecific esterase using alpha naphthyl acetate as substrate.¹⁶ The monocyte populations used in all experiments described contained <2% OKT3-positive, >98% LeuM3-positive, and >98% nonspecific esterase-positive cells.

Monocyte-conditioned medium preparation. Fresh or cryopreserved separated monocyte populations were cultured at 5×10^4 cells/mL for two days in alpha minimum essential medium (GIBCO, Grand Island, NY) containing 6% fetal bovine serum (Hyclone, Logan, UT) and 1 ng/mL endotoxin (LPS) (lipopolysaccharide B, *S. typhosa*, (DIFCO). The conditioned media were harvested and stored frozen at -20°C for assay.

Recombinant human IL-1. Human recombinant IL-1 (hrIL-1)

containing amino acids 71 through 269 and having a molecular weight of 24.5 kD (ROO6B) or another recombinant preparation (ROO6T) containing amino acids 112 through 269 and having a molecular weight of 17.0 kD were obtained as previously described.^{13,17} Briefly, hrIL-1-producing bacteria were grown at 37 °C and lysed, and the hrIL-1 was purified by sequential ion exchange and either gel-filtration chromatography or high-performance liquid chromatography (HPLC). The hrIL-1 was stored at -70 °C in a 0.15 mol/L phosphate-buffered saline, pH 5.8. The identity of the purified hrIL-1 was confirmed by amino acid composition and sequence of the amino terminal heptapeptide. Protein concentration was determined by the Bradford method using bovine serum albumin (BSA) as standard. Purity was assessed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) with Coomassie blue or silver staining. The hrIL-1 was estimated to be greater than 99% pure.

Fibroblast conditioned medium preparation. Human lung fibroblasts (CCL 202) were obtained from the American Type Tissue Culture Collection (Rockville, MD) and cultured in Dulbecco's Modified Eagle's Medium (DMEM) (GIBCO) supplemented with 10% fetal bovine serum (Hyclone). Fibroblasts from the first to the tenth passage were used, and the cell density ranged from 1 to 5 × 10⁴ cells per square centimeter. Cells were subcultured by brief (one-minute, 37 °C) treatment with 0.05% trypsin/0.02% disodium EDTA (wt/vol in PBS) and resuspended in fresh DMEM plus 10% fetal bovine serum and reseeded at a 1:5 dilution in 35-mm culture plates. At least 24 hours were allowed to elapse after initial seeding or subculture to obtain confluence before an experiment was begun. For assay, the fibroblast cell culture was replaced with 10% to 50% monocyte-conditioned medium, with or without a 1:100 dilution of the IgG fraction of rabbit antihuman IL-1,¹⁸ various concentrations of hrIL-1, or control medium diluted with fibroblast culture medium (FCM), and the cultures were returned to the incubator for an additional 24 hours. As controls, hrIL-1 alone, MCM alone, and FCM in the absence of hrIL-1 or MCM were incubated for 24 hours prior to assay. After 24 hours, the medium was aspirated and centrifuged (200 × g, five minutes), and the supernatants stored at -20 °C until tested.

Bone marrow cell preparation. Bone marrow cells were obtained by aspiration from the posterior iliac crest of healthy volunteers who had given informed consent. Unseparated nucleated buffy coat cells were obtained by centrifugation of whole bone marrow aspirates at 1,500 rpm for ten minutes, and isolation of the white cells that overlay the red cell layer. Low-density (LD) cells (1.077 g/mL) were obtained after separation on Ficoll-Hypaque (Pharmacia, Uppsala) at 1,500 rpm for 30 minutes, washed three times, and resuspended in Iscove's modified Dulbecco medium (IMDM) (GIBCO) containing 10% fetal bovine serum. Cells were further separated into nonadherent low-density (NALD) cells after incubation on plastic tissue culture dishes (Falcon, Oxnard, CA) for 90 minutes at 37 °C and 5% CO₂. NALD cells were collected by gently swirling the dishes and slowly removing the suspension cells. NALD cells prepared in this manner routinely contained <2% nonspecific esterase-positive cells. To deplete T lymphocytes, NALD cells were further separated into E-rosette-positive (E+) populations according to a method modified from Weiner et al¹⁹ as described previously.²⁰ Nonrosetting cells were separated by centrifugation through Ficoll-Hypaque. The purity of the NALD T lymphocyte-depleted fraction (NALDT⁻) was analyzed by indirect immunofluorescence with OKT3 or OKT11a as described above. The NALDT⁻ marrow cell fraction contained <2% OKT11a-positive cells.

BFU-E and CFU-GEMM assay. Bone marrow cells were plated at 1 × 10⁵ for LD and NALD cells and 4 × 10⁴ for NALDT⁻ cells in 35-mm Lux standard tissue culture dishes containing a 1-mL mixture of IMDM, 1% methylcellulose, 30% FBS, and 5 × 10⁻⁵ mol/L 2-mercaptoethanol. Cultures contained 0.1 mmol/L bovine hemin (Eastman Kodak Co, Rochester, NY) for CFU-GEMM colonies, while BFU-E were cultured without hemin.^{20,21} Human urinary erythropoietin (Toyoba, New York) or recombinant erythropoietin (Amgen, Thousand Oaks, CA) 1 unit/mL and the conditioned mediums to be tested were added to the dishes on day 0. Results were comparable using the two preparations of erythropoietin. Dishes were incubated at 37 °C in a humidified atmosphere flushed with 5% CO₂ and lowered (5%) O₂ for 14 days, at which time colonies were scored for BFU-E and CFU-GEMM. Lowered oxygen

tension was obtained using an oxyreducer (Reming Bioinstruments, NY).²¹ The criteria for evaluating BFU-E colonies have been given elsewhere.^{20,21} Mixed (CFU-GEMM) colonies contained erythroid cells with granulocytes and macrophages and sometimes megakaryocytes.

Statistical analysis. Levels of significance for comparisons between samples were determined using the Student's *t* distribution. The results are expressed as mean ± 1 standard error of the mean (SEM) of four or five plates per point for each experiment.

RESULTS

Both human monocyte-conditioned medium (MCM) and human recombinant interleukin 1 (hrIL-1) were shown to induce confluent fibroblast cultures to produce and release

stimulators of BFU-E and CFU-GEMM in nine different experiments using seven different target bone marrow preparations. Stimulation occurred whether the target bone marrow was depleted of high-density cells (Table 1, two separate experiments using two different target bone marrow populations), high-density cells plus adherent cells (Table 2, two separate experiments using two different target bone marrow cells), or high-density cells plus adherent cells plus T lymphocytes (Table 3, five different experiments using three different target bone marrow cells). Colony growth was significantly greater ($P < 0.005$) when bone marrow cultures were stimulated by supernatants of fibroblasts cultured in the presence of MCM or hrIL-1 when compared to supernatants of fibroblasts or monocytes cultured in medium alone.

** Resulting fibroblast-conditioned medium after stimulation by human recombinant IL-1 previously incubated with antibody to IL-1.

Erythroid BFU-E colonies stimulated with FCM(MCM) or with FCM(hrIL-1) were much larger in size than the erythroid colonies in the absence of FCM(MCM) or FCM(hrIL-1). The effects of MCM or hrIL-1 required intact fibroblasts, since mixtures of FCM and MCM contained no more stimulatory activity than FCM or MCM alone (Group 13, Table 1). In the absence of Epo or Epo plus hemin, FCM(MCM) or FCM(hrIL-1) did not stimulate any BFU-E or CFU-GEMM colonies, but they did stimulate numerous CFU-GM colonies. Thus, in experiment 1 reported in Table 2, FCM(MCM 25%) stimulated 112 ± 3 day 7 and 64 ± 1 day 14 CFU-GM colonies while FCM(hrIL-1, 140 ng/mL) stimulated 108 ± 3 day 7 and 59 ± 4 day 14 CFU-GM colonies, respectively. Similar results were previously reported for the stimulation of CFU-GM by IL-1-induced fibroblast-conditioned medium.¹³

To rule out the possibility that monocyte-conditioned medium or fibroblast-conditioned medium contained inhibitors for BFU-E and CFU-GEMM growth which were inactivated, allowing for the expression of enhanced colony growth, the following study was performed (Table 4). We assessed the effects of MCM, FCM and FCM(MCM) on erythroid and mixed colony formation stimulated by Epo or Epo plus hemin in the presence of 5637-conditioned medium. Medium conditioned with 5637 has been shown to be appropriate for the detection of suppressor factors.²² As seen in Table 4, none of the conditioned medium-suppressed colony formation by 5637-conditioned medium and the FCM(MCM) actually enhanced colony formation to a level equal to or slightly higher than that of FCM(MCM) in the absence of 5637-conditioned medium. (Compare group 6, experiments 2 and 3, Table 3 with group 4, Table 4).

Maximal colony formation by BFU-E and CFU-GEMM occurred when fibroblast cultures were stimulated by 70 to 140 ng/mL hrIL-1 (24.5 kD), 1.25 to 5.0 ng/mL hrIL-1 (17.0 kD) or 25% to 50% MCM. Conditioned medium obtained from fibroblasts cultured in the presence of increasing concentrations of hrIL-1 (35 to 140 ng/mL or 0.625 to 5.0 ng/mL) and MCM (10% to 25%) resulted in dose-

response increases in colony formation by BFU-E and CFU-GEMM.

As further proof that the activity found in monocyte-conditioned medium was due to IL-1 production by monocytes, studies were conducted using an antibody to IL-1. A 1:100 dilution of anti-IL-1 completely abolished the stimulation of CFU-GEMM by FCM(MCM 25%), while significantly reducing the enhancement of BFU-E colony formation. This same antibody completely abolished the stimulation of CFU-GEMM and BFU-E seen with fibroblast-conditioned medium collected in the presence of hrIL-1 (Tables 2 and 3). In addition, using this same IL-1 antibody, we tested to see if background erythroid colony formation stimulated in the presence of Epo or Epo plus hemin could be reduced by preincubation of the cells with IL-1 antibody. Cells were incubated for one hour with antibody to IL-1 (1:100 final dilution) in the presence of Epo or Epo plus hemin, or were incubated for one hour with McCoy's medium in the presence of Epo or Epo plus hemin. The cells were then plated without washing so that the antibody to IL-1 or control medium were plated also. Erythroid growth and CFU-GEMM growth were unchanged (BFU-E 63 ± 3 v 64 ± 3 and CFU-GEMM 5 ± 1 v 5 ± 1) when cells were incubated in the absence or presence of antibody to IL-1, respectively.

DISCUSSION

Assays are available to detect early human clonogenic progenitors that give rise to large erythroid colonies (BFU-E),¹ and colonies containing erythroid cells, granulocytes, megakaryocytes, and macrophages (CFU-GEMM).² Growth of these early progenitor cells depends on the presence of a source of burst-promoting activity (BPA) or conditioned medium obtained from leukocytes of patients with hemochromatosis cultured in the presence of 1% phytohemagglutinin. A number of different cell types including monocytes or macrophages,^{3,4} T lymphocytes,^{5,6} and endothelial cells⁷ have been reported to produce BPA. Recent studies on regulatory cell interactions have reported that monocytes produce a factor (monokine) which stimulates production of BPA by endothelial cells.¹² A similar cell-to-cell relationship has been proposed for GM-CSA production¹¹ and we have recently identified interleukin 1 (IL-1) as one monocyte product which stimulates fibroblasts to produce GM-CSA.¹³ The results of the present study show that fibroblasts are also capable of producing stimulating activities for BFU-E and CFU-GEMM colony formation. The production of this stimulating activity by fibroblasts requires prior induction by a monocyte product which we have identified as IL-1. Fibroblasts cultured in the presence of monocyte-conditioned medium or human recombinant IL-1 stimulated significantly greater BFU-E and CFU-GEMM colony growth when compared to supernatants of fibroblasts, monocytes, or IL-1 cultured alone. Both FCM(MCM) and FCM(hrIL-1) stimulated BFU-E and CFU-GEMM colony formation in a dose-dependent fashion with maximal colony formation occurring when fibroblasts were stimulated by 25% to 50% MCM, 70 to 140 ng/mL hrIL-1 (ROO6B), or 1.25 to 5

ng/mL hrIL-1 (ROO6T). In addition, a polyclonal rabbit antibody specific for human monocyte IL-1 completely abolished CFU-GEMM colony-stimulating activity while completely reducing the enhancing activity for BFU-E by FCM(hrIL-1) and almost completely reducing the enhancing activity for BFU-E by FCM(MCM).

The presence of inhibitors in monocyte-conditioned medium or fibroblast conditioned medium to erythroid and mixed colony growth appear unlikely, since neither MCM nor FCM suppressed colony growth stimulated by 5637 human bladder carcinoma-conditioned medium. The action of FCM(MCM) and FCM(hrIL-1) on BFU-E and CFU-GEMM colony growth do not appear to require monocytes or T lymphocytes in the marrow population containing BFU-E and CFU-GEMM, since results were similar when the target bone marrow population was depleted of both adherent cells and T lymphocytes.

Because FCM(hrIL-1) contains stimulators for CFU-GM, BFU-E, and CFU-GEMM, it is possible that all of

these actions are brought about by the presence of one or more factors. In this regard, human recombinant GM-CSF has been shown to stimulate BFU-E as well as CFU-GM.²³ Similarly, a pluripotent hematopoietic colony-stimulating factor (pluripotent CSA) has been purified from conditioned medium of the human bladder carcinoma cell line 5637.²⁴ This pluripotent CSF supports the growth of human mixed colonies, granulocyte-macrophage colonies, and early erythroid colonies and induces differentiation of the human promyelocytic leukemic cell line HL-60 and the murine myelomonocytic leukemic cell line WEHI-3B (D+). Whether the resulting fibroblast-conditioned medium stimulated by IL-1 and reported here contains one or more of these CSFs must await purification studies.

ACKNOWLEDGMENT

We wish to thank Scott Cooper for excellent technical assistance in setting up the bone marrow colony assays and Jeanie Wood for preparation of the manuscript.

Platelet Aggregation in Whole Blood From Patients With Glanzmann's Thrombasthenia

By Michael E. Burgess-Wilson, Stephen R. Cockbill, Geoffrey I. Johnston, and Stanley Heptinstall

We examined platelet aggregation in platelet-rich plasma (PRP) and in whole blood from two patients with Glanzmann's thrombasthenia. In PRP, aggregation was measured by monitoring the changes in light absorbance that occurred in response to aggregating agents; to measure platelet aggregation in whole blood, we used a platelet counting technique. In PRP, the patients' platelets showed defective aggregation in response to ADP, adrenaline, arachidonic acid (AA), and collagen, but normal agglutination occurred in response to ristocetin. In whole blood, however, platelet aggregation in response to the aggregating agents appeared to be either very similar to that which

occurred in blood from normal subjects or only slightly reduced. There was a reduced response to all concentrations of ADP and to low concentrations of collagen but a normal response to all concentrations of adrenaline, AA, and higher concentrations of collagen. Conversely, there seemed to be an increased agglutination response to ristocetin. The abnormality in our two patients with Glanzmann's thrombasthenia probably lies in the inability of their platelets to form large, macroscopic aggregates rather than in platelet aggregation *per se*.

© 1987 by Grune & Stratton, Inc.

GLANZMANN'S thrombasthenia is a rare bleeding disorder characterized by defective platelet aggregation but with a normal platelet count.¹ Platelets from patients with this condition either do not aggregate or aggregate very poorly in response to agents such as ADP, adrenaline, arachidonic acid (AA), and collagen. Platelets from such patients agglutinate normally in response to ristocetin,^{2,3} and this has been used to aid the diagnosis of the condition. Defective platelet aggregation is believed to result from a markedly reduced amount of a complex of glycoproteins (the glycoprotein IIb/IIIa complex) on the platelet surface.⁴ This glycoprotein complex is essential for normal platelet aggregation but plays no part in ristocetin-induced platelet agglutination.

Previous studies in which platelet aggregation in Glanzmann's thrombasthenia was compared with platelet aggregation in healthy controls involved the use of platelet-rich plasma (PRP), in which aggregation is measured by following the changes in light absorbance that occur. With this technique, macroscopic platelet aggregates must form before the light absorbance of the PRP falls. It is now possible to measure platelet aggregation in whole blood by counting the number of single platelets (ie, unaggregated platelets) using a whole-blood platelet counter.^{5,6} Because the technique relies on the determination of the number of single platelets that remain in the blood rather than the size of the platelet aggregates that form, it is an extremely sensitive means of detecting platelet aggregates composed of relatively few platelets. In the present investigation, we compared platelet aggregation in PRP (measured with light absorbance) and

whole blood (measured with the platelet counting technique) from patients with Glanzmann's thrombasthenia. The results obtained using whole blood were compared with those obtained for healthy controls.

MATERIALS AND METHODS

Materials. Adenosine 5'-diphosphate (ADP, sodium salt) adrenaline, and arachidonic acid (AA, grade 1 from porcine liver) were obtained from Sigma Chemical (St Louis). ADP and adrenaline were dissolved in saline before use; AA was converted to the sodium salt before use by dissolving it in 0.1 mol/L of sodium carbonate. Collagen (suspended equine collagen fibrils) was obtained from Hormon-Chemie and used as directed. Ristocetin sulphate was obtained from H. Lundbeck and dissolved in saline. Saline was 150 mmol/L of sodium chloride from Travenol Laboratories. The solution of citrate that was used to anticoagulate blood was 3.8% (wt/vol) trisodium citrate dihydrate. M148 (a monoclonal antibody directed against the glycoprotein IIb/IIIa complex) was a gift from Professor R.M. Hardisty, Institute of Child Health, London, and was used at a final dilution of 1:2,000. A control murine antibody 791T/36 (human osteogenic sarcoma cell-line) was a gift from Dr M. Price, Cancer Research Laboratories, University of Nottingham, England.

Subjects. Blood samples were taken from a sister and brother, designated as patient 1 and patient 2 throughout, aged 17 and 19 years, respectively, who had a similar history of mild bruising and bleeding. The diagnosis of Glanzmann's thrombasthenia had been made by Dr F.E. Preston (Department of Haematology, Royal Hallamshire Hospital, Sheffield, England) on the basis of clinical history and the pattern of platelet aggregation in PRP characteristic of the condition. When examined, the patients exhibited prolonged bleeding times (30 and 21 minutes, respectively), but clot retraction was normal as were the whole blood platelet counts.

Blood samples were also taken from six healthy controls (three men and three women with an age range of 18 to 42 years) to obtain a set of normal values for platelet aggregation in whole blood. The tests on these samples were carried out using the same protocol as that used for the two patients.

Blood collection. Blood was collected with minimum venous stasis from the antecubital vein into polypropylene syringes using a 19 gauge, 2-inch needle, and aliquots (9 mL) were dispensed into polystyrene tubes that contained 1 mL of citrate. Some of the citrated blood was centrifuged at 180 g for 10 minutes to prepare PRP, and the blood from which the PRP had been removed was then centrifuged at 1,200 g for 20 minutes to obtain platelet-poor plasma. The latter was used to adjust the platelet count in the PRP to 300 × 10⁹ platelets/L.

Measurements of platelet aggregation. Platelet aggregation in PRP was studied using the aggregometer and technique described by Adams and colleagues.⁷ Changes in light absorbance were recorded using a pen recorder.

Platelet aggregation in whole blood was assessed by determining the number of single platelets that remained in the blood after adding an aggregating agent to a sample. The number of single platelets present was counted using an Ultra-Flo 100 Whole Blood Platelet Counter and the technique described by Fox and co-workers.⁶ In brief, samples (500 μ L) of blood were placed in small polystyrene tubes, and the tubes were placed in a water bath at 37 °C. After 2 minutes, a small aliquot of the blood was removed for platelet counting, a metal stirrer bar was placed in each tube, and the blood was stirred at 1,000 rpm. After a further 2 minutes, another small aliquot was removed for platelet counting, and a solution of the aggregating agent under investigation was then added. Stirring was then continued, and further small aliquots were removed for platelet counting at 2-minute intervals up to 6 minutes after addition of the aggregating agent. The results obtained were expressed as the percentage of single platelets lost from the blood relative to the number of platelets present immediately prior to the addition of aggregating agent.

Inhibition of platelet aggregation by M148. The monoclonal antibody, M148, binds to the glycoprotein IIb/IIIa complex on the surface of normal platelets and inhibits aggregation induced by ADP, adrenaline, AA, and collagen in both PRP and in whole blood.⁸ In some experiments, M148 (at a final dilution of 1:2,000) was added to blood from the two patients with Glanzmann's thrombasthenia 2 minutes before the aggregating agent; aliquots were then removed for platelet counting at 20-second intervals up to 2 minutes after addition of the aggregating agent. To facilitate this quicker subsampling technique, the aliquots (15 μ L) were taken into fixative as described by Bevan and colleagues⁹ to be counted later on the Ultra-Flo 100. The results were compared with those obtained using a control murine antibody (791T/36).

Measurement of glycoprotein expression. Expression of the glycoprotein IIb/IIIa complex on the surface of platelets from the patients was measured using the monoclonal antibody, M148,¹⁰ combined with the technique of flow cytofluorimetry. After 240 μ L samples of PRP were incubated with M148, aliquots containing 2×10^6 platelets were removed to tubes containing a fluorescent-labeled rabbit anti-mouse immunoglobulin as described previously.¹¹ After a further incubation, immunofluorescence analysis was carried out using the FACS IV Flow Cytofluorimeter.¹²

Microscopic examination of platelet aggregates. After samples of blood from both patients with Glanzmann's thrombasthenia and samples of blood from a healthy control were stirred with ADP (10 μ mol/L), adrenaline (10 μ mol/L), AA (0.2 mmol/L), collagen (6 μ g/mL), and ristocetin (2 mg/mL), each for 6 minutes, the blood was smeared on a glass slide and stained with May-Grunwald-Giemsa stain. The tails of the blood smears were then examined for platelet/platelet aggregates under a light microscope. The effect of preincubating blood from the patients and controls with M148 or control antibody prior to adding 5 μ mol/L of ADP was also determined.

RESULTS

Platelet aggregation in PRP. The light absorbance of samples of PRP from the patients with Glanzmann's thrombasthenia either did not fall or fell only slightly when adrenaline, ADP, AA, or collagen was added to the PRP. In contrast, adding ristocetin to PRP from the patients induced a large fall in light absorbance; this was accompanied by the appearance of macroscopic platelet aggregates in the sample.

Examples of the results obtained for the two patients are given in Fig 1, these results having been seen on more than one occasion.

Platelet aggregation in whole blood. In contrast to the results obtained in PRP, platelet aggregation did occur when ADP, adrenaline, AA, or collagen was added to whole blood from the patients with Glanzmann's thrombasthenia. Table 1 shows the percentage loss of single platelets 6 minutes after the addition of aggregating agents to samples of whole blood obtained from the two patients and the controls. There was a reduced response in both patients, as compared with the mean control value, to all concentrations of ADP (Fig 2) and to the lower concentrations of collagen (0.3 and 1.0 μ g/mL) and AA (0.1 mmol/L) but a normal response to all concentrations of adrenaline and higher concentrations of collagen (3 and 6 μ g/mL) and AA (0.2 mmol/L). There was an increased agglutination response to the lower concentration of ristocetin used.

When samples of whole blood from the patients with Glanzmann's thrombasthenia were preincubated with M148, the platelet aggregation induced by ADP, adrenaline, and collagen, was virtually abolished (Fig 3).

Glycoprotein expression. After immunofluorescence analysis of platelets incubated with M148 followed by a fluorescent-labeled immunoglobulin, the number of glyco-

Fig 1. The changes in light absorbance that occurred in platelet-rich plasma (PRP) (480 μ L) that had been stirred at 37 °C for 2 minutes followed by the addition of various aggregating agents (20 μ L). Typical traces obtained from both of the patients on one occasion are shown. For each aggregating agent, the first of each pair of traces is that obtained for patient 2 and the second is that for patient 1.

Table 1. Percentage of Single Platelets Lost Six Minutes After Addition of Aggregating Agents to Samples of Whole Blood Stirred at 37 °C

Aggregating Agent	Patient 1	Patient 2	Controls
Saline	2	4	10 ± 6
ADP (0.5 µmol/L)	9	8	22 ± 5
ADP (1.0 µmol/L)	4	6	30 ± 14
ADP (2.0 µmol/L)	26	15	52 ± 22
ADP (10.0 µmol/L)	40	28	90 ± 9
Adrenaline (0.2 µmol/L)	16	10	10 ± 7
Adrenaline (0.5 µmol/L)	18	19	16 ± 9
Adrenaline (1.0 µmol/L)	21	25	20 ± 9
Adrenaline (2.0 µmol/L)	24	38	26 ± 10
Adrenaline (5.0 µmol/L)	30	39	33 ± 17
AA (0.1 mmol/L)	4	2	43 ± 33
AA (0.2 mmol/L)	92	93	95 ± 3
Collagen (0.3 µg/mL)	11	7	20 ± 14
Collagen (1.0 µg/mL)	31	18	80 ± 29
Collagen (3.0 µg/mL)	89	90	96 ± 1
Collagen (6.0 µg/mL)	92	94	97 ± 1
Ristocetin (1.0 mg/mL)	96	99	20 ± 13
Ristocetin (2.0 mg/mL)	97	99	95 ± 2

Control values are mean ± SD (n = 6).

protein IIb/IIIa complexes on the surface of platelets from patients 1 and 2 were calculated to be 450 and 1,600, respectively. This compares with a mean value of 17,300 for platelets from normal subjects.⁸ We have already shown that these patients have platelets that are deficient in glycoprotein

Fig 2. The percentage of single platelets lost from whole blood stirred at 37 °C following the addition of different concentrations of ADP at time 0. The results shown are for patient 1 (○) and patient 2 (□). The control values (Δ) are mean ± SD (n = 6).

Fig 3. The percentage of single platelets lost from whole blood stirred at 37 °C following the addition of various aggregating agents at time 0. The blood had been preincubated for 2 minutes with either M148 or a control antibody. The results are for patient 1 in the presence of either M148 (●) or control antibody (○) and for patient 2 in the presence of either M148 (■) or control antibody (□). Unfortunately, only data for patient 1 were obtained for ristocetin-induced agglutination.

IIb/IIIa and that the deficiency does not reside in a subpopulation of cells.¹¹

Microscopy. Samples of blood to which aggregating agents had been added were examined for the presence of platelet aggregates by light microscopy. Platelet aggregates were present in whole blood from the patients with Glanzmann's thrombasthenia as well as in blood from the normal control. When blood from the patients or controls was incubated with M148 before adding ADP, only single platelets were seen.

DISCUSSION

The results of our studies on platelet aggregation in PRP in which we used light absorption as a means of measuring the platelet aggregation that occurred are entirely consistent with those obtained by other workers who have investigated patients with Glanzmann's thrombasthenia.¹⁻³ Aggregation was clearly defective in PRP from the two patients that we investigated. We were therefore surprised to find that the loss of single platelets induced by the addition of aggregating agents to whole blood from the patients appeared to be very similar to the loss obtained from healthy controls or was only slightly reduced. The reduced response to ADP was >1 SD at lower concentrations and >2 SDs at the highest concentra-

tion ($10 \mu\text{mol/L}$), whereas the reduced responses to collagen and AA were only seen at the lower concentrations tested.

By preincubating whole blood from the patients with M148, we were able to confirm that the single platelets that were lost when an aggregating agent was added to whole blood were indeed taking part in aggregate formation. The addition of this monoclonal antibody virtually abolished the platelet loss that occurred following addition of ADP, adrenaline, or collagen to blood from the patients with Glanzmann's thrombasthenia. As further confirmation that platelet aggregation was occurring in whole blood, we looked directly for platelet aggregates in blood from the patients using light microscopy. Platelet aggregates were observed in all the samples to which an aggregating agent had been added. In addition, M148 prevented aggregate formation.

We consider that the apparent discrepancy between results obtained in whole blood and PRP in this investigation relates to the differences in the two techniques that were used to measure the aggregation that occurred. The light absorbance of PRP falls only when very large platelet aggregates (that are visible to the naked eye and must contain many thousands of platelets) form. Conversely, the number of single platelets in whole blood falls as soon as the single platelets take part in aggregate formation whatever the size of the aggregates that develop. The defective platelet aggregation in PRP from patients with Glanzmann's thrombasthenia may occur because the aggregates that form are relatively small. We believe that it is unlikely that the different results in PRP and whole blood relate to the presence of RBCs in the latter, but this possibility has not been excluded.

Although the patients we investigated had platelets that contained markedly reduced amounts of surface-expressed glycoprotein IIb/IIIa complex (3% and 9% of normal for patients 1 and 2, respectively), the platelets were not completely devoid of the glycoprotein complex. In addition, clot retraction occurred in coagulated whole blood from these patients. Thus, according to the definition of Caen,¹³ our patients probably have type II Glanzmann's thrombasthenia. Platelets from patients with type I Glanzmann's thrombasthenia have undetectable amounts of the glycoprotein complex and clot retraction is absent in coagulated blood.

Although Nurden and colleagues¹⁴ recently reported the presence of measurable amounts of glycoprotein IIb and/or glycoprotein IIIa on the platelets of patients with type I Glanzmann's thrombasthenia, they proposed that it was the number of functional glycoprotein IIb/IIIa complexes expressed on the surface of the platelet that was important in discriminating between the two subgroups. It is probable that the small amounts of complex that are present on our patients' platelets allow partial platelet aggregation that is detectable in our whole blood system but not in PRP. In view of the reduced platelet aggregation that occurs in response to ADP and low concentrations of collagen in whole blood from these patients, it will be interesting to discover if platelet aggregation is further reduced in whole blood from patients with a more severe glycoprotein IIb/IIIa complex deficiency. It must be noted that in our investigation platelets from patient 1 aggregated slightly more extensively in both PRP and whole blood than did platelets from patient 2, despite having a lesser amount of the glycoprotein IIb/IIIa complex available and a longer bleeding time. This lack of correlation between glycoprotein expression, platelet aggregation, and bleeding time in these two patients may be caused by the close similarity of the patients with regard to both clinical and laboratory parameters, however.

In the cases of Glanzmann's thrombasthenia we have studied, only relatively small amounts of glycoprotein IIb/IIIa were expressed, and the deficiency resides in all the platelets rather than in a subpopulation.¹¹ We have suggested that it is the amount of glycoprotein IIb/IIIa on the surface of platelets that determines the size of the aggregates that are produced in response to an aggregating agent and that the true deficiency in Glanzmann's thrombasthenia relates to the size of the aggregates produced rather than to aggregation per se. The precise relationship between aggregate size and glycoprotein IIb/IIIa expression needs to be explored by further experimentation.

ACKNOWLEDGMENT

We are grateful to Dr F. E. Preston for kindly allowing us to study his patients, and to Professor R. M. Hardisty and Dr M. Price for gifts of antibodies.

Purification and Properties of Bacterially Synthesized Human Granulocyte-Macrophage Colony Stimulating Factor

By Antony W. Burgess, C. Glenn Begley, Gregory R. Johnson, Angel F. Lopez, D. James Williamson, Jean Jacques Mermod, Richard J. Simpson, Albert Schmitz, and John F. DeLamarter

Human granulocyte-macrophage colony stimulating factor (GM-CSF) has been synthesized in high yield using a temperature inducible plasmid in *Escherichia coli*. The human GM-CSF is readily isolated from the bacterial proteins because of its differential solubility and chromatographic properties. The bacterially synthesized form of the human GM-CSF contains an extra methionine residue at position 1, but otherwise it is identical to the polypeptide predicted from the cDNA sequence. The specific activity of 2.9×10^7 units/mg of protein for purified bacterially synthesized human GM-CSF indicates that despite the lack of glycosylation, the molecule is substantially in its native conformation. This molecule stimulated the same number and type of both seven- and 14-day human bone marrow colonies as the CSF α preparation from human placental conditioned medium. Human GM-CSF had no activity on murine bone marrow or murine leukemic cells. There was

no detectable, direct stimulation of adult human erythroid burst forming units (BFU-E) by the bacterially synthesized human GM-CSF. Although impure preparations containing native human GM-CSF (eg. human placental conditioned medium) stimulated the formation of mixed colonies, even in the presence of erythropoietin, the bacterially synthesized human GM-CSF failed to stimulate the formation of mixed colonies from adult human bone marrow cells. The bacterially synthesized human GM-CSF increased *N*-formyl-methionyl-leucyl-phenylalanine (FMLP)-induced superoxide production and lysozyme secretion. Antibody-dependent cytotoxicity and phagocytosis by human neutrophils was stimulated by the bacterially synthesized human GM-CSF and eosinophils were also activated in the antibody-dependent cytotoxicity assay.

THE IDENTIFICATION of the cDNA clone for murine granulocyte-macrophage colony stimulating factor (mGM-CSF)¹ enabled the production of the biologically active polypeptide by COS cells^{1,2} and bacteria.^{3,4} The cDNA mGM-CSF also led to the isolation of full-length cDNAs for human GM-CSF⁵ (hGM-CSF) and confirmed the identity of the human CSF cloned from a COS cell expression library.⁶ The hGM-CSF expressed by COS cells⁷⁻⁹ appears to encode all of the in vitro biological activities associated with CSF α ¹⁰ prepared from human placental conditioned medium¹¹ and conditioned medium from the U5637 cell line.¹² The COS cell-derived hGM-CSF stimulated the proliferation and differentiation of granulocyte, macrophage, and eosinophil progenitor cells^{8,9} as well as the function of neutrophils.¹² Thus, the simian-derived carbohydrate moiety does not appear to alter the cellular specificity of the hGM-CSF.^{8,9} However, it is possible that a hGM-CSF polypeptide with a simian, hamster, or yeast carbohydrate moiety will be antigenic in vivo or that the different carbohydrate moiety will influence the in vivo distribution of the GM-CSF. We have produced hGM-CSF in bacteria and purified the polypeptide without any attached carbohydrate. These studies define the conditions necessary for the preparation and purification of bacterially synthesized hGM-CSF, the specific activity of the molecule, and its activities on progenitor as well as mature cells. In part, these results emphasize the continuing need to understand the interactions between subsets of human bone marrow cells.^{13,14}

MATERIALS AND METHODS

Preparation and Purification of Bacterially Synthesized Human GM-CSF

hGM-CSF cDNA was isolated from a library constructed using mRNA from the human monocytic cell line U937¹⁵ by screening candidate clones with a nick-translated probe derived from the coding sequences of mGM-CSF.³ The deduced amino acid sequence of the U937 hGM-CSF was identical to hGM-CSF produced by the leukemic cell line Mo(6) with the exception of the conservative

substitutions of a methionine by an isoleucine (amino acid 80 of the mature protein) and a threonine by an isoleucine (amino acid 100 of the mature protein). The amino acid for residue 100 of the mature protein deduced from a genomic clone was also isoleucine.¹⁶ These differences between cDNAs and the genomic sequences may represent allelic variations. Sequences coding for the mature hGM-CSF protein were placed in an *Escherichia coli* vector behind an inducible promoter as previously described for the mGM-CSF gene.³ The construction took advantage of the unique restriction endonuclease site (*Hga* I) located 58 nucleotides before the codon for the first amino acid of the mature protein (alanine). An oligonucleotide linker was synthesized to replace the deleted codons with the addition of an amino-terminal methionine codon to initiate translation in the prokaryote host. This linker contained substitutions of adenosine wherever retention of the native amino acid allowed.³ The noncoding 3' distal end of the cDNA was cleaved at the unique *Bal* I restriction endonuclease site and ligated to a similarly blunt-ended site (*Sma* I) in the expression vector. Once introduced into a suitable *E. coli* host (LON-, HPTR-) the induction of hGM-CSF production was initiated by temperature shift (28 °C to 48 °C). hGM-CSF accumulated over four hours to 8% to 10% of the total cell protein. Bacteria were harvested and GM-CSF extracted essentially as described for mGM-CSF.³ In induced cells hGM-CSF accumulated

in dense bodies which were collected by centrifugation following breakage of the cells. After washing the pellet was resuspended in 6 mol/L guanidinium hydrochloride and 2 mmol/L β -mercaptoethanol and chromatographed over G-100 Sephadex in the same buffer. The highly purified hGM-CSF fractions were collected and the denaturant and reductant removed by slow dialysis against neutral Tris buffer. The final purification step was gradient elution from a reverse-phase support at pH 2.1 on an Ultrapore RPSC column (4.6×7.5 cm) from Beckman, Santa Clara, CA.¹⁷ The final purity of the hGM-CSF was assessed by sodium dodecyl sulfate (SDS) gel electrophoresis¹⁸ and automated gas phase amino acid sequence analysis.¹⁹ The protein concentration for the specific activity calculation was determined by amino acid analysis.²⁰

Assays on Bacterially Synthesized Human GM-CSF

The purified hGM-CSF preparation (approximately 0.3 mg/mL in acetonitrile [30%]: trifluoroacetic acid [0.1%]: water [70%]) was diluted 1:100 in 10% normal saline containing fetal calf serum (FCS) (10%, vol/vol) and 0.1 mL of the diluted sample (or serial dilutions thereof) was assayed in the 1-mL semisolid bone marrow cultures.

Human marrow cultures. Marrow and peripheral blood samples were obtained with the prior informed consent of patients according to a protocol approved by the Ethics Committee of the Royal Melbourne Hospital. Light density (ρ 1.070 g/cc) or nonadherent light density bone marrow cells (30,000) from patients with no hematological disease were cultured in 35-mm Petri dishes using 1 mL of Dulbecco's Modified Eagle's Medium and a final concentration of 20% FCS and 0.3% agar.²¹ Cultures were incubated for up to 14 days at 37 °C in a fully humidified atmosphere of 10% CO₂ in air. For erythroid colony formation, 1-mL cultures containing 30,000 light density (<1.070 g/cc) mononuclear or nonadherent mononuclear bone marrow cells in Iscove's Modified Dulbecco's Medium and a final concentration of 25% FCS and 0.3% agar were established. Cultures were incubated for 14 days in a fully humidified atmosphere of 5% CO₂ in air.

Colony formation (clones of more than 40 cells) was scored at 35 $\times$ magnifications using a dissection microscope after seven or 14 days of incubation. To determine the cellular composition of the resulting colonies, intact cultures were fixed using 2.5% glutaraldehyde and methanol and, after drying, were stained with Luxol Fast-Blue/hematoxylin. Colony classification was performed at 400 $\times$ magnifications.

Units of colony stimulating activity were calculated from the linear portion of the dose-response curve assigning 50 U/mL to the concentration stimulating the formation of 50% maximal colony numbers.

The human placental conditioned medium (HPCM) Stage II used in these experiments was prepared as described previously.¹⁰ The semipurified CSF α and β fractions were obtained using phenyl-Sepharose chromatography of medium conditioned by the human bladder cancer cell line U5637, using methods described previously.²²

Murine assays. Serial dilutions of bacterially synthesized hGM-CSF samples (0.1 mL) were added to agar cultures of 75,000 C57BL adult marrow cells in FCS (20%) or 20,000 12-day CBA fetal liver cells in cultures containing human plasma (20%). Control cultures contained 400 units of purified mGM-CSF,¹⁷ Multi-CSF,²³ G-CSF,²⁴ M-CSF,²⁵ or saline. Colony formation was scored after seven days of incubation. To determine whether bacterially synthesized hGM-CSF could initiate but not sustain colony formation by murine hematopoietic cells, 400 units of Multi-CSF were added after two days of incubation to replicate cultures of fetal liver cells and the cultures scored after a total incubation period of seven days. After

scoring, cultures were stained with Luxol Fast-Blue/hematoxylin and colonies classified according to cellular composition.

Microwell assays using the continuous hematopoietic cell lines 32D cl.3²⁶ (kindly supplied by Dr J. Greenberger, Boston) and FDC-P1²⁷ (kindly supplied by Dr T.M. Dexter, Manchester, England) were performed in microtiter trays using 200 cells per well in 10 μ L of Dulbecco's Modified Eagle's Medium with FCS (10%, vol/vol). Serial dilutions of 5 μ L of each test sample were added and direct cell counts performed after 48 hours of incubation.

To determine whether bacterially synthesized hGM-CSF was able to induce the differentiation of WEHI-3B(D⁺) cells,²⁸ serial dilutions of the hGM-CSF samples (0.1 mL) were added to agar cultures of 300 WEHI-3B(D⁺) cells. The percentage of colonies exhibiting differentiation was determined after seven days of incubation.²⁹ Control cultures contained 0.1 mL of serial dilutions of either serum from C57BL mice injected three hours previously with 5 μ g endotoxin³⁰ or semipurified human CSF β .¹⁰

Functional Activation of Mature Cells

Purification of human neutrophils and eosinophils. These cells were obtained from the peripheral blood of healthy volunteers after dextran sedimentation and centrifugation on a hypertonic gradient of Metrizamide (Nyegaard, Oslo) as previously described.³¹ The purity was higher than 95% for neutrophils and higher than 92% for eosinophils. The cells were resuspended in Eagle's Minimal Essential Medium supplemented with 10% FCS, 20 mmol/L HEPES buffer, and antibiotics.

Antibody-dependent cell mediated cytotoxicity assay. ADCC was performed as previously described.³² In brief, 40 μ L of ⁵¹Cr-labeled, trinitrophenyl (TNP)-coupled P815 cells (4×10^3) were incubated with 24 μ L of rabbit IgG anti-TNP (Rehovot, Israel), 80 μ L of purified human neutrophils or eosinophils (1.3×10^5) as effector cells, and 16 μ L of bacterially synthesized hGM-CSF for two and one half hours at 37 °C in V-bottom microtitre plates. Percent cytotoxicity was calculated from the formula: (test – control)/total – control $\times$ 100, where "control" was the ⁵¹Cr released by P815 cells in the presence of medium alone, and "total" was the ⁵¹Cr released by the addition of 5% Triton X-100.

Superoxide production. Purified neutrophils were incubated with medium or different concentrations of bacterially synthesized hGM-CSF for two hours at 37 °C. After this, 150 μ L of cells (10^6) were mixed with 100 μ L freshly prepared cytochrome-C (Sigma, St Louis, type VI, 12.4 mg/mL), 100 μ L N-formyl-methionyl-leucyl-phenylalanine (FMLP) (10^{-6} mol/L) and made up to 1 mL with medium. The mixtures were then incubated at 37 °C for five minutes, after which the cells were rapidly cooled, centrifuged at 4 °C, and the supernatants transferred to plastic disposable cuvettes. Superoxide production was measured by the reduction of cytochrome-C³³ using an extinction coefficient of 21.1 mmol/L⁻¹.³⁴

The medium used throughout these assays was RPMI (free of phenol red) containing 2% FCS. In control experiments, bacterially synthesized hGM-CSF did not reduce cytochrome-C in the absence of cells, and superoxide dismutase (Sigma) completely abolished the reduction of cytochrome-C. The results are expressed as the means of triplicate determinations $\pm$ 1 standard deviation.

Phagocytosis assay. This assay measured the phagocytosis of serum-opsonized baker's yeast and was performed as described.⁹ In brief, 100 μ L purified neutrophils (2×10^7 /mL) were incubated with 250 μ L baker's yeast, 100 μ L diluted fresh autologous serum and 50 μ L bacterially synthesized hGM-CSF or medium with FCS for one hour at 37 °C. After this, the cells were centrifuged at 4 °C, resuspended in 50 μ L of cold PBS and smeared onto a slide. When eosinophils were tested, this assay was scaled down because of the relatively low numbers of eosinophils routinely obtained. The vol-

umes were 20 μ L of cells (10^7 /mL), 50 μ L of baker's yeast, 20 μ L of freshly obtained human serum and 10 μ L of bacterially synthesized hGM-CSF or medium. After incubation, cytochrome preparations were made. Slides were fixed in methanol and stained with Giemsa before being examined for the number of cells showing different numbers of phagocytosed yeast. The data are expressed as percentages after counting a minimum of 200 cells per slide.

Degranulation assay. This was carried out as previously described.³⁵ Briefly, purified neutrophils (5×10^6 /mL) pretreated with cytochalasin-B (Sigma) were incubated with different stimuli for 15 minutes at 37 °C. To these mixtures different concentrations of FMLP (Sigma) were added and the cells incubated a further 30 minutes at 37 °C. After incubation the cells were centrifuged and the released lysozyme assayed against *Micrococcus lysodeikticus* (Sigma). The optical density at 450 nm was measured at ten-second intervals for three minutes. Triplicate determinations (every ten seconds) were made and the amount of lysozyme released was calculated from a standard curve generated by egg white lysozyme (Sigma). Maximum values were obtained by using supernatants from neutrophils lysed with Triton X-100.

RESULTS AND DISCUSSION

Induction and Purification of Bacterially Synthesized Human GM-CSF

Recombinant hGM-CSF was produced in *E. coli* under the regulation of a heat-inducible promoter. After GM-CSF synthesis was induced by raising the culture temperature, the protein accumulated in aggregates as dense bodies within the cells. Following weakening of the cell walls by lysozyme treatment, cells were disrupted in a French pressure cell. The aggregates were collected by centrifugation and resuspended in 6 mol/L urea. hGM-CSF was initially purified from the solution by chromatography over Sephadex G100. Aliquots (2 to 5 mL) of the low-molecular weight fraction from the gel filtration containing GM-CSF were diluted with an equal volume of aqueous trifluoroacetic acid (0.15%, vol/vol) and loaded onto a reversed-phase Ultrapore RPSC column equilibrated with aqueous trifluoroacetic acid (0.15%, vol/vol). Several proteins were eluted from the column (Fig 1), but the earliest eluting material was not associated with biological activity. SDS-polyacrylamide gel analysis of the column fractions (Fig 2) indicated that the 16,000-dalton protein associated with the biologic activity was pure. Amino acid sequence analysis of 200 pmoles of the purified hGM-CSF

Fig 1. Reversed phase high-performance liquid chromatography purification of bacterially synthesized human GM-CSF.

Fig 2. Electrophoretic analysis of purified bacterially synthesized human GM-CSF.

yielded a single amino acid at each cycle; the first residue detected was methionine, and the next 16 cycles yielded the sequence expected from the nucleotide sequence.⁶ Thus, this product is different from the natural molecule in that not only is the carbohydrate moiety missing, but there is also an *N*-terminal methionine which is not removed during synthesis. The results of the quantitative amino acid analysis of the purified bacterially synthesized hGM-CSF were in excellent agreement with the composition predicted from the nucleotide sequence. The optical density at pH 2.1 in the presence of acetonitrile (30%, vol/vol), together with the amino acid analysis yielded a molar extinction coefficient of 2×10^4 moles⁻¹ cm⁻¹. Attempts to determine a precise specific activity for the purified bacterially synthesized hGM-CSF are complicated by the wide variation in sensitivity of different bone marrow samples and variations in the frequency of colony-forming cells for different human bone marrow samples. The standard assays were performed using between 30,000 and 50,000 bone marrow cells per milliliter. Eight separate bone marrows stimulated by the purified bacterially synthesized hGM-CSF yielded an average specific activity of $2.9 \pm 1.9 \times 10^7$ U/mg of protein after seven days in culture. The same four samples yielded a specific activity of $2.9 \pm 0.7 \times 10^7$ U/mg of protein after 14 days in culture. The ratio of day-7 to day-14 colonies was dependent on the bone marrow sample and varied from 0.3 to 1.6. In general, impure samples of hGM-CSF (eg, human placental conditioned medium or bladder carcinoma conditioned medium) contained a mixture of both hGM-CSF (CSF α) and hGM-CSF (CSF β). The CSF β preparation preferentially stimulates colony formation at day 7; thus, the ratio of the number of colonies at day 7 to day 14 (approximately three) tends to be considerably higher than for GM-CSF and the CSF α preparation. Similarly, a mixture of the bacterially synthesized GM-CSF and the CSF β preparation generally stimulates more day-7 colonies than either stimulus by itself. Each molecule preferentially stimulates a defined subset of GM-progenitor cells. After 14 days in culture the bacterially

synthesized hGM-CSF stimulated as many colonies as preparations of CSF α ¹⁰ from human placental conditioned media.¹¹

Our method of preparation and purification indicates that the bacterially synthesized hGM-CSF is stable in 6 mol/L urea, as well as at pH 2.1 in the presence of 40% acetonitrile. Indeed, at low pH the bacterially synthesized hGM-CSF appears to retain its full biologic activity indefinitely. However, initial attempts to store this hGM-CSF at neutral pH in the absence of urea have led to precipitation of the molecule.

Concentration Dependence of Colony Formation

The purified hGM-CSF was titrated and assayed on eight separate bone marrow aspirates: both the seven-day (Fig 3A) and 14-day (Fig 3B) cultures indicated that maximal stimulation of colony formation was achieved at concentrations of 500 pmol/L or greater. Half-maximal stimulation occurred between 60 pmol/L and 120 pmol/L and the minimum detectable hGM-CSF concentration using the semisolid agar assay was 10 pmol/L for both time points.

The direct action of bacterially synthesized hGM-CSF on human colony forming cells was examined by transfer of day-5 clones to plates containing the bacterially synthesized hGM-CSF, human placental conditioned medium, or saline (Fig 4). The bacterially synthesized hGM-CSF continued to stimulate colony growth and GM-CSF is undoubtedly one of the active hematopoietic growth factors in the HPCM.

Morphology of Colonies

In two separate experiments, the types of colonies stimulated by the bacterially synthesized hGM-CSF have been compared to the colony types obtained with unfractionated HPCM, CSF α , and CSF β (Table 1). The bacterially synthesized hGM-CSF stimulated pure neutrophil (G), macrophage (M) and eosinophil (Eo) colonies as well as mixed granulocyte-macrophage colonies. At day 7 all preparations of CSF stimulated mainly granulocytic colonies. However, the bacterially synthesized hGM-CSF and CSF α also stimu-

Fig 3. Effect of GM-CSF on colony growth for eight normal human bone marrow samples. (A) Day 7; (B) Day 14. The results are presented as the mean and standard deviations. The results of assays with optimal concentrations of CSF α and CSF β prepared from human placental conditioned medium are also displayed.

Fig 4. Growth of colonies after transfer of Day 5 human bone marrow colonies to recipient plates with either bacterially synthesized hGM-CSF, human placental conditioned medium (HPCM), or saline. The solid circles represent colonies composed of neutrophils, macrophages, or both, and the open circles represent the eosinophil colonies.

lated a small proportion of Eo colonies. As expected, for both HPCM and CSF α the proportions of pure M and pure Eo colonies were increased at 14 days. Thus, the bacterially synthesized hGM-CSF stimulated a similar range of colonies to the CSF α .

The bacterially synthesized hGM-CSF was used in an attempt to stimulate the hematopoietic progenitor cells in murine bone marrow. Even at a concentration of 2 nmol/L no colonies or clusters were observed after seven days in culture. The hGM-CSF did not enhance the survival of multi-CSF-responsive progenitor cells in the delayed addition assay. Similarly, there was no effect of this hGM-CSF on several murine cell lines which were known to respond to murine hematopoietic growth factors: WEHI-3BD⁺ (G-CSF-responsive) did not differentiate in response to hGM-CSF, FDCP1 (GM-CSF- or Multi-CSF-dependent) and 32D cells (Multi-CSF-dependent) did not proliferate in the presence of hGM-CSF (data not shown).

Effect of Bacterially Synthesized Human GM-CSF on Erythroid Progenitor Cells

The colony types stimulated by human tissue-derived conditioned media (eg, human placental conditioned medium, [HPCM]) have been studied extensively using a range of partially purified hematopoietic progenitor cells.^{36,37} Studies by Sieff et al with a hGM-CSF partially purified from transfected COS cell conditioned medium indicated

Table 1. Morphology of Human Bone Marrow Colonies Stimulated by Bacterially Synthesized hGM-CSF

Incubation Time	Experiment Number	Stimulus	Mean Number of Colonies*	Colony Type (%)

* 3×10^4 light density nonadherent human bone marrow cells were cultured in 1 mL of semisolid agar and examined after seven and 14 days. The agar cultures were fixed and stained and the colonies analyzed to determine the proportion of G, neutrophil; M, macrophage; GM, neutrophil-macrophage and EOS, eosinophil colonies.

some potentiating effect of the GM-CSF on BFU-E proliferation.³⁸ Similarly, their results with highly purified fetal BFU-E suggested that pure hGM-CSF stimulates the proliferation and differentiation of these cells. However, the initial results with purified mGM-CSF on murine fetal liver progenitor cells³⁹ indicated that only a subset of the fetal BFU-E appeared to be responsive to GM-CSF and the proportion of adult BFU-E responsive to GM-CSF appears to be quite small.

In a report of experiments with the COS cell-derived recombinant hGM-CSF and human fetal progenitor cells,⁴⁰ it was noted that even though the BFU-E represented 30% of the cell population when the culture cell density was below 100 cells/mL no colonies developed in the presence of GM-CSF. It is possible that the GM-CSF stimulated accessory cells to produce BFU-E stimulating factors. Initially, we attempted to detect the effect of the bacterially synthesized GM-CSF on BFU-E in mononuclear and nonadherent mononuclear cells from human bone marrow cells (Tables 2 and 3).

The light density mononuclear cells from human bone marrow did not produce erythroid colonies in the absence of erythropoietin (Table 2). In the presence of erythropoietin, erythroid colonies developed. Addition of a source of CSF (HPCM) did not change the frequency of erythroid colonies. However, the neutrophil-, eosinophil-, and macrophage-containing colonies appeared as expected. Identical effects were observed with the bacterially synthesized human GM-CSF (at both 2.5 nmol/L and 50 nmol/L). When the addition of erythropoietin was delayed for three to four days, there was a slight decrease in erythroid colony numbers but neither HPCM nor the bacterially synthesized hGM-CSF influenced the survival of these erythroid progenitors.

*See footnote to Table 2 for technical details of these experiments.

After removing the adherent cells, HPCM but not the bacterially synthesized hGM-CSF increased the cloning efficiency of the erythroid progenitor cells (Table 3). When the adherent cells are removed, a subset of the erythroid progenitors appears to be stimulated by HPCM. Even when the erythropoietin is added three or four days after the initiation of the cultures with HPCM this synergistic effect of HPCM can be observed (Table 3). Again, approximately half the erythroid colonies appear to be stimulated by a molecule present in human placental conditioned medium. It is unlikely that GM-CSF is related to this phenomenon, as the bacterially synthesized hGM-CSF did not modulate the number of 14-day erythroid colonies.

When both erythropoietin and hGM-CSF were present, their effects appeared to be independent. No extra erythroid colonies were observed compared to the cultures stimulated with erythropoietin alone. In contrast, unfractionated HPCM consistently increased (two- to fourfold) the number of erythroid colonies developing from the nonadherent light density mononuclear bone marrow cells. Mixed erythroid colonies⁴¹ were only observed in the presence of the unfractionated HPCM. Neither the bacterially synthesized GM-CSF, the erythropoietin, nor the mixture of both were able to stimulate human mixed colonies. At concentrations greater than 500 pmol/L, the bacterially synthesized GM-CSF stimulated the same range of nonerythroid colonies as the optimum concentration of human placental conditioned medium.

The lack of erythroid (BFU-E) potentiation by hGM-CSF could be due to the presence of accessory cells which suppress the GM-CSF-responsive BFU-E. However, the previously reported effects of GM-CSF may also be indirect (ie, via a GM-CSF-responsive cell which produces an erythroid factor). Understanding the interactions between the different cells controlling human erythropoiesis will require a detailed analysis of the proliferation of single cells and subsequent cell-mixing experiments.

Action of Bacterially Synthesized hGM-CSF on Mature Hematopoietic Cells

As well as stimulating the proliferation of the myeloid progenitor cells, the hGM-CSF purified from the Mo cell line is able to stimulate some of the functions of mature neutrophils^{8,9,12} and eosinophils.²⁰ We have measured the effect of the bacterially synthesized GM-CSF on four parameters of granulocyte function: superoxide (O_2^-) production,^{33,34} phagocytosis,⁹ lysozyme secretion,³⁵ and antibody-dependent cell-mediated cytotoxicity.³² At concentrations of hGM-CSF above 10 pmol/L both purified neutrophils and eosinophils were stimulated maximally to kill tumor target cells, and stimulation of killing was still detectable at 1 pmol/L (Fig 5). The concentration dependence of neutrophil and eosinophil activation was very similar (Fig 5). A similar concentration-dependent effect on neutrophil function was obtained by Weisbart et al⁸ for the inhibition of neutrophil migration using either recombinant hGM-CSF produced by transfected monkey COS cells or the hGM-CSF purified from the Mo cell line. Thus, our results show that hGM-CSF does not require carbohydrate moieties for its action in vitro.

COS cell-derived hGM-CSF has been previously found to stimulate phagocytosis.⁹ A comparison of the effects of *E. coli*-synthesized hGM-CSF on neutrophil phagocytosis of yeast organisms in the presence or absence of serum is displayed in Fig 6. In the presence of fresh human serum, the bacterially synthesized hGM-CSF (4 nmol/L) activated large numbers of neutrophils to phagocytose several yeast particles (Fig 6). Heating of human serum for 30 minutes at 56 °C abrogated the GM-CSF stimulation of neutrophils to phagocytose heat-killed yeast (data not shown), suggesting that complement is the opsonic factor present in human serum, and that the stimulation by hGM-CSF is dependent on the presence of this opsonin. There was a 50% increase in the number of neutrophils which phagocytosed the heat-killed yeast (Fig 6).

The response of neutrophils to bacterial products also appears to be stimulated by hGM-CSF. The secretion of lysozyme by neutrophils was dependent on the presence of chemotactic agents (Table 4). In the absence of a chemotactic peptide such as FMLP,⁴² there was no activation of lysozyme secretion. However, preincubation of neutrophils with the bacterially synthesized hGM-CSF enhanced the FMLP-induced release of lysozyme from purified neutrophils by 60% (Table 4). At low concentrations of the chemotactic peptide (10^{-8} mol/L) the hGM-CSF was more

Fig 5. Effect of GM-CSF concentration on the ability of human neutrophils or eosinophils to kill antibody-coated P815 mastocytoma cells.

Fig 6. Effect of GM-CSF (4 nmol/L) on the ability of human neutrophils to phagocytose yeast.

effective than lipopolysaccharide.⁴³ Bacterially synthesized hGM-CSF also enhanced FMLP-mediated stimulation of superoxide production by human neutrophils (Fig 7). In the absence of hGM-CSF and FMLP, superoxide production by human neutrophils was not detectable. The chemotactic peptide by itself induced O_2^- production to 1.3 nmoles/min/ 10^6 cells. In the absence of FMLP, hGM-CSF had little or no effect on O_2^- production (Fig 7). However, preincubation of neutrophils with GM-CSF followed by FMLP increased the amount of O_2^- production sevenfold over the level induced by FMLP alone. The interaction between FMLP and GM-CSF was concentration dependent: the maximal rate of O_2^- production was achieved at 200 pmol/L, but the synergism was still evident when the hGM-CSF concentration was 10 pmol/L (Fig 7).

Thus, GM-CSF is capable of enhancing at least three separate systems in human neutrophils: the release of both lysozyme and O_2^- (upon stimulation with FMLP), phagocytosis of yeast (complement-mediated), and killing of tumor target cells (antibody-dependent).⁴⁴ In its ability to activate mature neutrophils, this bacterially-synthesized hGM-CSF behaves very similarly to the recombinant hGM-CSF produced by transfected monkey COS cells (ref 9, and Lopez et al, in preparation).

We have demonstrated the action of purified, bacterially synthesized hGM-CSF on a range of hematopoietic progenitor and mature cells. This GM-CSF has a specific activity in the same range as the recombinant GM-CSF purified from medium conditioned by Mo cells³⁸ or the medium from COS cells transfected with cDNA for hGM-CSF¹² (Table 5). Thus, neither the addition of the extra *N*-terminal methionine residue, nor the absence of carbohydrate appear to affect the in vitro activity of hGM-CSF. The detailed morphological distribution of the colonies stimulated by both the *E. coli*-synthesized and COS cell-stimulated hGM-CSF

varies considerably and is dependent on the specific bone marrow being assayed. However, both forms stimulate predominantly neutrophilic granulocyte colonies at day 7 (Table 5), and by day 14 most of the colonies contain macrophages. There is a similar increase in the proportion of eosinophil colonies with both GM-CSFs by day 14 (Table 5).

Our attempts to show the direct effects of hGM-CSF on erythroid progenitor cells (ie, BFU-E) have been unsuccessful. Despite the availability of a pure stimulus such as the bacterially synthesized hGM-CSF, the purity of our hematopoietic progenitor cells has been insufficient to prove that the hGM-CSF acts directly on progenitors of the erythroid series. At least one study using COS cell-derived recombi-

Table 5. Comparison of *E. coli*-Derived and COS Cell-Derived hGM-CSF

Property	hGM-CSF					
	<i>E. coli</i> -Derived			COS Cell-Derived		
Apparent molecular weights	16,000			19,000–22,000		
Specific Activity (U/mg/ 10 ⁴ bone marrow cells)	1 × 10 ⁷			1 × 10 ⁷ –5 × 10 ⁷		
Morphology of myeloid colonies	(%)			(%) ⁴		
		Day 7	Day 14		Day 8	Day 14
	G	70	31	G	70	8
	GM	4	8	GM	20	16
	M	24	47	M	5	51
	Eo	2	14	Eo	5	25
BFU-E Responsiveness	No effect			(a) Stimulated “directly” (b) No effect (c) Inhibitory in the presence of erythroid potentiating activity		
Responsive mature cells	G, Eo			G, Eo, and monocytes ⁴⁶		

Abbreviations: G, granulocytes; GM, granulocyte-macrophages; M, monocytes; Eo, eosinophils.

nant hGM-CSF also reported that there was no effect on BFU-E, although in the presence of erythroid potentiating activity and erythropoietin, the human GM-CSF appeared to inhibit BFU-E.⁴⁵ Others appear to have shown effects of COS cell-derived hGM-CSF on highly purified BFU-E.⁴⁰ It will be necessary to study the effects of pure hGM-CSF on single BFU-E before we can be sure that the hGM-CSF has a direct effect on erythropoiesis.

The availability of *E. coli*-synthesized hGM-CSF with essentially identical biologic properties to natural hGM-CSF will provide sufficient quantities of this molecule for clinical testing. The absence of any foreign carbohydrate moiety should reduce problems with immunologic neutralization

during clinical applications. The absence of carbohydrate side chains has allowed the development of monoclonal antibody reagents which can distinguish between the native hGM-CSF (as is present in human placental conditioned medium) and the bacterially synthesized GM-CSF. Thus, it will be possible to monitor the serum levels of the administered GM-CSF during patient treatment. The bacterially synthesized hGM-CSF should be suitable both for studies aimed at increasing the rate of recovery of myeloid cells after cytotoxic treatment and for attempts to activate neutrophils and/or eosinophils in patients with poor neutrophil function, eg, older patients, immunosuppressed patients or patients with chronic infections.

New Abnormalities in the Morphology, Cell Surface Receptors, and Electrolyte Metabolism of In(Lu) Erythrocytes

By Mark M. Udden, Masato Umeda, Yukiko Hirano, and Donald M. Marcus

The In(Lu) phenotype is inherited as an autosomal dominant trait and is characterized by suppression of the Lutheran, P₁, i, and Au^a erythrocyte blood group antigens. We have developed a monoclonal antibody (L21) that strongly agglutinates all erythrocytes except In(Lu), and we have identified eight In(Lu) individuals among 42,000 blood donors tested. Studies of two families confirmed the dominant mode of inheritance and revealed several new features of this phenotype. The erythrocytes of all five affected individuals from the two families exhibited diminished hemagglutination by the lectin concanavalin A, although they reacted normally with several other lectins. The erythrocytes of two affected individuals in one family exhibited marked acanthocytosis. The erythrocytes of the *proposita* of the other family exhibited a mild degree of

poikilocytosis, but the cells of the other two affected individuals in this family had normal morphology. The osmotic fragility of fresh In(Lu) erythrocytes was normal, but after incubation for 24 hours at 37 °C in plasma the In(Lu) cells exhibited a marked increase in resistance to osmotic lysis. During the incubation period the erythrocytes lost K⁺ and their total cation content was diminished. These data indicate that in addition to the suppression of blood group antigens noted previously, the In(Lu) phenotype includes a variety of morphological abnormalities and a defect in electrolyte metabolism. The use of L21 and similar monoclonal antibodies provides a more sensitive means of detecting In(Lu) erythrocytes than typing with human anti-Lu^b antisera.

© 1987 by Grune & Stratton, Inc.

THE MAJOR ANTIGENS of the Lutheran blood group system are the codominant antigens Lu^a and Lu^b.¹ Two rare Lu(a-b-) phenotypes have been described. One is inherited as an autosomal recessive trait; these erythrocytes contain no detectable Lu^a or Lu^b antigens and the expression of other blood group antigens is normal.¹⁻⁵ The other Lu(a-b-) phenotype, In(Lu), exhibits several exceptional features: it is inherited as an autosomal dominant, the expression of antigens from other blood group systems (P₁, i, and Au^a) is suppressed, and weak expression of the Lu^a and Lu^b antigens can be detected by adsorption and elution of anti-Lu^a and anti-Lu^b from erythrocytes.^{1,4-7} No information is available about the biochemical nature of the Lu^a and Lu^b antigenic determinants.

Recently several monoclonal antibodies have been described that strongly agglutinate all erythrocytes except In(Lu) cells, which give weak or negative reactions; recessive Lu(a-b-) cells react normally. The H86 monoclonal antibody (H86 mAb) described by Knowles et al⁸ was elicited by immunization of mice with the human T cell leukemia line HSB-2, and A3D8 mAb was raised by immunization with Sezary T cells.^{9,10} Both antibodies bind to most human blood mononuclear cells, and A3D8 immunoprecipitates 80-kD

and 170-kD proteins from erythrocytes. In(Lu) erythrocytes contain only traces of immunoprecipitable 80-kD protein but the 170-kD protein appears to be present in increased abundance.¹⁰

We have produced a monoclonal antibody (L21) that also reacts very weakly with In(Lu) cells and we have used this antibody to identify individuals with the In(Lu) phenotype. We describe here newly identified morphologic and functional abnormalities of In(Lu) erythrocytes.

MATERIALS AND METHODS

Erythrocytes. Fresh samples of venous blood were obtained in heparinized tubes and stored at 4 °C in Alsever's solution.

Antibodies and lectins. Monoclonal antibody L21 (IgG₁, κ) was produced by intravenous immunization of BALB/c mice with pooled umbilical cord red cells, and it was obtained in the same fusion that yielded five monoclonal antibodies against glycophorin A. Details of the fusion and cloning procedures were published previously.¹¹ When tested against a large panel of erythrocytes in two blood group reference laboratories, Ortho Diagnostic Systems, Raritan, NJ, and Gamma Biologicals, Houston, TX, L21 strongly agglutinated all erythrocytes except those of In(Lu) phenotype. Monoclonal antibody A3D8⁹ was kindly provided by Drs M. Telen and B. Haynes, and H86⁸ was a gift from Dr R. Knowles. Concanavalin A (Con A), *Lens culinaris*, *Ricinus communis*, and *Arachis hypogaeae* were purchased from Vector Laboratories, Burlingame, CA, and E-Y Laboratories, San Mateo, CA.

Immunological tests. Hemagglutination tests were performed by incubating 50 μL of serial twofold dilutions of monoclonal antibodies or lectins with 50 μL of a 1% erythrocyte suspension for one hour at room temperature in a 96-well microtiter plate (Dynatech Laboratories, Alexandria, VA). L21 was labeled with ¹²⁵I by the iodogen procedure¹² and the radiolabeled antibody was separated from free ¹²⁵I by gel filtration on a PD-10 column (Pharmacia Fine Chemicals, Piscataway, NJ).

Binding of radiolabeled antibodies to erythrocytes. Erythrocytes were washed three times with phosphate-buffered saline (150 mmol/L NaCl, 20 mmol/L PO₄, pH 7.4, PBS) and were suspended in PBS containing 10 mg/mL bovine serum albumin (1% BSA-PBS). 2 × 10⁸ erythrocytes in 0.5 mL 1% BSA-PBS were incubated with ¹²⁵I-labeled L21 for one hour at room temperature with occasional shaking, washed three times with 1% BSA-PBS, and counted in a gamma counter (LKB, Bromma, Sweden). For the competitive binding assay, ¹²⁵I-labeled L21 was mixed with varying

concentrations of A3D8 or H86 and the binding of ^{125}I -labeled L clone to erythrocytes was measured.

Erythrocyte morphology and osmotic fragility. Freshly drawn blood anticoagulated with EDTA was used for preparation of Wright's-stained peripheral blood films. Erythrocytes were prepared for scanning electron microscopy by washing three times with 150 mmol/L NaCl containing 5 mmol/L Tris, pH 7.4, and then fixed in buffer containing 3% glutaraldehyde. The fixed erythrocytes were attached to polylysine hydrobromide-coated glass coverslips and then dehydrated by immersion in a series of acetone solutions increasing in concentration from 50% to 100% acetone. They were then critical point-dried from acetone and liquid CO_2 , sputter-coated with gold, and examined in a JEM 100C Teuscan electron microscope (JEOL, Peabody, MA) in the secondary electron imaging mode at 20 kilo-electron volts. Erythrocyte osmotic fragility was determined on fresh and incubated whole blood anticoagulated with heparin as described by Beutler.¹³ Erythrocyte Na^+ and K^+ concentrations were determined by atomic absorption spectroscopy in the emission mode using an atomic absorption spectrometer (Perkin-Elmer, Norwalk, CT). Measurements were made on fresh and incubated erythrocytes washed four times with isotonic MgCl_2 and then lysed in 0.1% LiCl. Other hematologic measurements, hemoglobin, WBC, and RBC counts were determined using a Baker Hematology Series 150 cell counter (Baker, Allentown, PA).

RESULTS

Expression of antigens and lectin receptors. Erythrocytes of types Lu(a+b+), Lu(a-b+), Lu(a+b-) and Lu(a-b-) were agglutinated by L21 at dilutions of 1:6,000 to 1:25,000. When the antibody, diluted 1:2,000, was used to test 42,000 blood donors, eight individuals were found whose red cells gave weak or negative reactions.¹⁴ Two In(Lu) donors and their relatives, family C and family S (Fig 1) were selected for further investigation. Erythrocytes from 11 donors from the two families were tested for hemagglutination by L21 and A3D8 (Table 1). Erythrocytes of the two

§Hemagglutination was not detected.

members of family S (II-1 and III-1) failed to react with both mAbs, and three members of family C (II-1, II-2 and III-1) gave weak agglutination with L21 and A3D8.

The direct binding of L21 to erythrocytes was measured by using radiolabeled L21 mAb. Erythrocytes from all five donors of the In(Lu) phenotype exhibited marked reduction of binding by L21 ($21.1 \pm 6.5\%$ of normal). Figure 2 shows typical binding curves obtained with erythrocytes from family C members. Two individuals with the In(Lu) phenotype (II-1 and II-2) showed marked reduction of binding compared to unaffected family members. Less suppression of binding (34% of normal) was observed with III-1 of family C (data not shown). The extent of the reduction in binding is consistent with the results obtained with the hemagglutination assays shown in Table 1, and the data suggest incomplete and variable suppression of the antigen by the In(Lu) gene.

The In(Lu) gene also inhibits the expression of the P_1 and i

Fig 2. Binding of ^{125}I -labeled L21 monoclonal antibody to erythrocytes of the C family. The erythrocytes of the probanda, III-1, were not tested on this occasion.

antigens, which are known to be carbohydrate structures.¹⁵⁻¹⁷ In order to study the effect of the In(Lu) gene on other carbohydrate structures, hemagglutination by several lectins was examined. All five In(Lu) members of both families exhibited reduced hemagglutination by concanavalin A (Table 2). Hemagglutination by other lectins (*Lens culinaris*, *Ricinus communis*, and *Arachis hypogaeae*), was normal (data not shown).

Erythrocyte morphology. In family S the In(Lu) phenotype was associated with acanthocytic erythrocytes as shown in Fig 3. The Wright's-stained peripheral blood films of In(Lu) individuals II-1 and III-1 (Figures 3A, 3C) show numerous acanthocytes whereas the unaffected family members had the expected discocyte morphology of normal erythrocytes. The In(Lu) individuals had other poikilocytes, but there were no Howell-Jolly bodies, targets, or siderocytes present to suggest an asplenic blood picture. Acanthocytes and other bizarre erythrocyte shapes were also observed when In(Lu) cells were washed free of plasma, fixed with glutaraldehyde and then viewed by scanning electron microscopy (Fig 4). The erythrocyte morphology of the members of family C was normal except for the proposita, whose cells demonstrated a mild degree of poikilocytosis and the pres-

ence of an occasional acanthocyte. Other common hematologic tests, including reticulocyte count, white blood cell count, packed cell volume, hemoglobin, red cell count, and the derived red blood cell indices were within normal limits in two In(Lu) individuals (family C, III-1 and family S, II-1). The absence of anemia and reticulocytosis suggests that the In(Lu) phenotype is not associated with significant hemolysis. The In(Lu) probands are healthy and have no past history or physical findings suggestive of significant illness. There was no clinical or laboratory evidence of renal, liver, or thyroid disease or abetalipoproteinemia.

Erythrocyte cations. Although the osmotic fragility of fresh In(Lu) erythrocytes was normal, incubation of these cells for 24 hours at 37 °C in plasma resulted in a significant resistance to osmotic lysis, in contrast to normal erythrocytes whose osmotic fragility increased after incubation in plasma. This striking difference in osmotic fragility is demonstrated in Fig 5, which compares the osmotic fragility curves of fresh and incubated red cells for an affected and a normal member of family S. Increased resistance to osmotic lysis was also observed when erythrocytes from the proposita of family C were incubated. Storage of In(Lu) erythrocytes for several hours at 4 °C did not affect these results.

Because resistance to osmotic lysis can occur as a consequence of cation depletion and cellular dehydration, the Na⁺ and K⁺ contents of fresh and incubated In(Lu) erythrocytes were determined (Table 3). Although In(Lu) and control cells had similar Na⁺ and K⁺ concentrations before incubation, significant K⁺ loss occurred during incubation of In(Lu) cells that was not seen in the controls. The K⁺ loss during incubation of erythrocytes from the family C proposita was partially offset by a gain in intracellular Na⁺. The total cation content of the two In(Lu) individuals was decreased, however, and may account for their relative resistance to osmotic lysis.

DISCUSSION

By use of a dilution of L21 mAb that strongly agglutinated normal erythrocytes and gave a weak or negative reaction

Fig 3. Photomicrographs (original magnification $\times 1000$) of Wright's-stained peripheral blood from family S. Acanthocytes are evident in In(Lu) individuals II-1 (A) and III-1 (C). Red cell morphology is normal in the non-In(Lu) members I-1 (B) and III-2 (D).

Fig 4. Scanning electron micrographs of washed erythrocytes from subject S, II-1 showing an acanthocyte in (A) (magnification $\times 10,350$) and a bizarre poikilocyte in (B) (magnification $\times 11,230$).

with In(Lu) cells, we were able to identify eight individuals with this phenotype among 42,000 donors tested in the Houston metropolitan region. Although the inheritance of this trait was studied in only two families, it is unlikely that any of these individuals represented the recessive Lu(a-b-) phenotype, because L21 reacts normally with erythrocytes of this phenotype. The frequency of the In(Lu) phenotype in our study, approximately 1:5,000, is similar to the frequency of 1:3,000 found by Shaw et al in Southeast England.¹⁸

The studies of these two families have revealed several new aspects of the In(Lu) phenotype: decreased agglutination of erythrocytes by Con A, and abnormal erythrocyte morphology and electrolyte metabolism. The reactivity of lectins with these erythrocytes was examined because two of the suppressed blood group antigens, P₁ and i, are known to have carbohydrate antigenic determinants.^{15,17} The diminished reactivity of In(Lu) cells with Con A is manifested primarily by a decreased strength of agglutination rather than a decreased agglutination titer. The diminished agglutination was not a consequence of abnormal erythrocyte morphology because the erythrocytes of the C family were not markedly abnormal in shape, and other samples of acanthocytic erythrocytes tested reacted normally with Con A and with the L21 and A3D8 mAbs.

In these two families the In(Lu) phenotype was associated with changes in erythrocyte morphology and osmotic fragility.

Fig 5. Osmotic fragility of In(Lu) erythrocytes from family S, subject II-1, compared to a normal family member, III-2. Nearly identical osmotic fragility is observed for fresh In(Lu) and control erythrocytes (O-O-O). In(Lu) RBC incubated at 37 °C for 24 hours in plasma (●-●-●) develop a population of cells resistant to osmotic lysis not seen in the incubated controls (Δ-Δ).

ty. In the S family acanthocytes and other bizarre poikilocytes were identified on routine peripheral blood films and confirmed by scanning electron microscopy of washed red blood cells. Another disorder of red blood cell antigen expression, the McLeod phenotype, is also associated with acanthocytosis.¹⁹ McLeod families, however, exhibit decreased expression of Kell red blood antigen, X-linked inheritance, and hemolysis. Other causes of acanthocytosis, including splenectomy, liver disease, and abetalipoproteinemia,²⁰ were also sought but were not identified. Thus the morphologic abnormalities seem to be another manifestation of the activity of the In(Lu) gene. The less striking erythrocyte changes observed in the proband of the C family (III-1), and the normal morphology of the two other affected members of this family suggests that the degree of red blood cell morphologic abnormality varies among different In(Lu) kindreds.

Although the two families described in this report differed in their degree of RBC morphologic change, they demonstrated similar changes in osmotic fragility. In both families the osmotic fragility of fresh In(Lu) erythrocytes was normal, whereas decreased osmotic fragility developed after incubation for 24 hours at 37 °C. The osmotically resistant incubated In(Lu) RBC were also K⁺-depleted when com-

pared to incubated normal controls. Because K^+ depletion usually results in dehydration of the erythrocyte, the K^+ loss observed after incubation of In(Lu) erythrocytes could explain the osmotic resistance, although RBC water content was not measured to verify this possibility.

What is the basic abnormality that underlies the In(Lu) phenotype? The studies of Telen et al¹⁰ have demonstrated that an 80-kD glycoprotein is immunoprecipitated by A3D8 from normal erythrocytes, and that only traces of this glycoprotein are immunoprecipitated from In(Lu) cells. It is not known whether the concentration of this protein is decreased in In(Lu) cells or whether the concentration of the protein is normal and epitope recognized by A3D8 is altered. It seems unlikely to us that this is the sole or principal abnormality of In(Lu) erythrocytes because of data pointing to abnormalities in other molecules. Band 3 is the major Con A-binding protein of human erythrocytes^{21,22} and it also carries the i antigenic determinant.²³⁻²⁵ The decreased expression of these receptors indicates an abnormality in the glycosylation of band 3. The P₁ antigenic determinant is expressed on glycolipids.¹⁵ In addition, there is evidence that the three monoclonal antibodies that react weakly with In(Lu) erythrocytes are directed at different epitopes. A3D8 and L21 agglutinate umbilical cord erythrocytes but H86 does not, and the receptor for H86 is protease-resistant but the receptors for L21 and A3D8 are protease-sensitive (refs 8 and 9, and Umeda and Marcus, unpublished observations).

We suggested previously¹⁵ that the basis of the In(Lu) phenotype is abnormal glycosylation of a common carbohydrate sequence that is present in many glycoproteins and in some glycolipids. The identification of decreased expression of the red cell Con A receptor lends further support to this

suggestion. Moreover, the occurrence of the determinants recognized by these monoclonal antibodies on several cell lineages, human erythrocytes, monocytes, and lymphocytes, and the presence of the L21 antigen on glycoproteins from several species, is more consistent with a carbohydrate than with a peptide determinant.

The designation In(Lu) reflects the first serological abnormality described in this phenotype, suppression of the Lu^a and Lu^b antigens. It is evident that the weak Lutheran antigens are only one of many biochemical and morphologic abnormalities displayed by this phenotype, and that the emphasis on the Lutheran antigens is misleading. Evidence for suppression of other high-frequency blood group antigens of In(Lu) erythrocytes was reported recently.²⁶ An important practical point is that the phenotype is more readily identified by the use of the new monoclonal antibodies than by screening for a weak Lu^b antigen. Human anti-Lu^b sera are very weak, as well as limited in supply, and it is difficult to determine accurately whether a weak Lu^b antigen represents the lower end of the normal distribution or a genetic abnormality. The availability of monoclonal antibodies for detection of the In(Lu) phenotype should facilitate biochemical studies of this interesting genetic abnormality.

ACKNOWLEDGMENT

The authors wish to express their deep appreciation to M. Schultz, A. Miller, L. Leu, and Pablo Fortes of the Gulf Coast Regional Blood Center, for their assistance. The authors wish to acknowledge the technical assistance of Robert Annand and the expert secretarial assistance of Charlene Shackelford in the preparation of this manuscript. Scanning electron microscopy was performed by Dr Joiner Cartwright, Department of Pathology, Baylor College of Medicine.

Divalent Cation-Dependent and Independent Surface Expression of Thrombospondin on Thrombin-Stimulated Human Platelets

By Martha L. Aiken, Mark H. Ginsberg, and Edward F. Plow

Thrombospondin (TSP), a platelet α -granule protein, becomes expressed on the surface of thrombin-stimulated platelets. The surface expression of this protein occurs through two distinct mechanisms. At low platelet concentrations (1×10^8 /mL), a divalent ion-independent, low-capacity mechanism predominates. At higher cell concentrations, a divalent ion-dependent, higher capacity mechanism prevails that can account for >90% of all the TSP surface expression measured. This mechanism

requires the presence of both calcium and magnesium (Ca + Mg). The dependence of the divalent ion-dependent surface expression on platelet concentration suggests that release of the molecule from the cell followed by its binding to the cell surface mediates this component of the endogenous TSP-platelet interaction. These data are consistent with a two-receptor model for the platelet surface expression of the endogenous TSP pool.

© 1987 by Grune & Stratton, Inc.

THROMBOSPONDIN (TSP) is a trimeric glycoprotein comprised of 180-kD mol wt subunits.¹ It is a major protein of platelet α -granules²⁻⁵ and is synthesized by a variety of cells including monocytes,⁶ fibroblasts,⁷ endothelial cells,^{8,9} and megakaryocytes.¹⁰ Although the role of TSP in the function of these various cell types remains to be elucidated, several lines of evidence suggest that TSP is involved in platelet function. TSP binds to fibrinogen,¹¹⁻¹³ and fibronectin,^{13,14} which are involved in platelet adhesion and aggregation.¹⁵⁻¹⁸ TSP agglutinates fixed RBCs, platelets, or platelet membranes to one another.¹⁹⁻²¹ In addition, anti-TSP antibodies inhibit fibrinogen binding to thrombin-activated platelets.²² Finally, both monoclonal²³ and polyclonal antibodies²⁴ to TSP can inhibit the aggregation of human platelets.

The capacity of TSP to participate in platelet aggregation implies that the molecule must be available at the cell surface. Direct evidence for surface expression of TSP has been obtained by using cell surface-labeling approaches^{5,25-27} and from the binding of radiolabeled polyclonal and monoclonal antibodies to platelets.^{28,29} Both approaches suggest that thrombin stimulation of platelets results in surface expression of TSP as a consequence of its secretion from α -granules. Beyond these basic observations, there is limited information as to the regulation of TSP surface expression, and controversy exists. Using surface radioiodination approaches, Phillips and co-workers²⁶ indicated that TSP surface expression was calcium dependent, whereas George

and co-workers^{5,25} were able to radioiodinate TSP on the surface of thrombin-stimulated platelets in the presence of EDTA. In view of these uncertainties, we undertook a quantitative assessment of TSP surface expression using a monoclonal antibody to TSP. This antibody, TSP1-1, is a particularly interesting probe for such analyses as it has been shown to inhibit the hemagglutinating activity of TSP.³⁰ An additional impetus for these analyses has been our recent characterization of the interaction of exogenously added TSP and platelets.³¹ In the present study, we sought to determine if the two receptor systems that mediate the interaction of exogenously added TSP are also involved in regulating the surface expression of the molecule.

MATERIALS AND METHODS

Monoclonal antibody production and isolation. TSP was purified by a modification of the method of Lawler and co-workers.^{1,32} In brief, fresh human platelets (25 U) were stimulated with thrombin at 3 U/mL. A releasate fraction was obtained by centrifugation, and this fraction was applied to a heparin-Sepharose column. TSP was eluted, and this fraction and the nonbinding fraction were pooled and rechromatographed on heparin-Sepharose, using the same protocol. The second 0.45 mol/L of NaCl eluate containing TSP was pooled and frozen at -70°C . The typical yield of TSP was 1 mg from each unit of platelets.

TSP1-1 was produced using standard protocols. In brief, Balb/c mice were immunized with 25 μg of TSP followed by a second boost of 25 μg injected 2 weeks later. On the fourth and fifth day prior to fusion, the animals were given 40 μg of TSP intravenously (IV). Spleen cells from these mice were fused with the myeloma cell line P3X63Ag8.653 at a spleen-myeloma cell ratio of 5:1. TSP antibody-producing hybrids were detected with solid-phase radioimmunoassay as described,³³ coating microwells with 2.5 $\mu\text{g}/\text{mL}$ of TSP. The positive clones were subcloned by limiting dilution, retested in the solid-phase radioimmunoassay, and recloned.

The selected TSP1-1 clone was injected into pristane-primed mice, and ascites fluid was harvested during a 2-week period. The ascites fluid was characterized by electrophoresis on cellulose acetate strips and yielded a single major band in the γ region, consistent with the monoclonal nature of the antibody. By Ouchterlony analysis with class-specific monoclonal antibodies, TSP1-1 was determined to be an IgG2a antibody with a κ light chain.

TSP1-1 was purified essentially as described by Ey and colleagues.³⁴ In brief, ascites fluid (20 mL) containing TSP1-1 was incubated with Protein-A Sepharose CL-4B (Pharmacia Fine Chemicals, Piscataway, NJ) for 18 to 20 hours at 4°C , with gentle agitation. Following the incubation, the slurry was centrifuged (120 g) for 5 minutes. The supernatant was removed, and the resin was resuspended in 0.1 mol/L of PO4, pH 8.0. The Protein A-

Sephacryl was then washed with the equilibration buffer, and the bound protein was eluted in a stepwise fashion with 0.1 mol/L of sodium citrate at pH 5.5, 4.5, and 3.5. The pH 4.5 fraction, which contained TSP1-1, was dialyzed against phosphate-buffered saline (PBS), and the purified antibody was stored at -20°C . Typically, 1 to 2 mg of TSP1-1 was obtained from each milliliter of ascites. The antibody was $\geq 95\%$ homogeneous as judged by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).

TSP1-1 was radiolabeled by a modified chloramine-T procedure³⁵ to a specific activity of $\sim 0.5 \mu\text{Ci}/\mu\text{g}$. Residual free iodine was removed by gel filtration on a PD-10 column (Pharmacia), equilibrated in and eluted with PBS. The protein concentration of the radiolabeled antibody was determined from the original protein concentration of the unlabeled protein, based on its absorption at 280 nm, and the precipitability of the radioactivity in 15% trichloroacetic acid prior to and after gel filtration. The precipitability of radioactivity in 15% trichloroacetic acid exceeded 98%, and protein recovery was routinely $>90\%$. The radiolabeled antibody (^{125}I -TSP1-1), as added to and as eluted from platelets (see below), exhibited a single band by SDS-PAGE (7.5% gels under nonreducing conditions) with a mobility corresponding to the isolated and nonlabeled antibody.

Platelet isolation. Washed human platelets were obtained as previously described.³⁶ In brief, 60 to 90 mL of fresh human blood were collected into acid-citrate-dextrose. This procedure was performed with the approval of our local Human Investigations Committee and the Department of Health and Human Services. The blood was centrifuged (120 g) for 20 minutes at 22°C . The platelet-rich plasma was removed and recentrifuged at 1,000 g at 22°C . The platelets were recovered as a pellet and resuspended in 2 mL of divalent ion-free Tyrode's buffer, pH 7.2, containing 2% bovine serum albumin, and subjected to gel filtration on Sepharose CL-2B ($2.5 \times 8 \text{ cm}$) (Pharmacia) equilibrated in the same buffer. The washed platelets were collected in $\sim 4 \text{ mL}$ and counted electronically in a Coulter Counter Model Zf (Coulter Electronics, Hialeah, FL). In some experiments, paraformaldehyde-fixed platelets were used. These were prepared as previously described.³⁷ Washed human platelets were incubated with thrombin at 0.25 U/mL for 5 minutes, and the agonist was inactivated with a tenfold excess of hirudin. Following platelet activation, paraformaldehyde was added to a final concentration of 0.05%. After 30 minutes at 22°C , 0.02 mol/L of NH_4Cl in 0.15 mol/L of NaCl, 0.02 mol/L of Tris, pH 7.2, was added in equal volume, and the platelets were centrifuged at 1,000 g for 15 minutes at 22°C . The supernatant was removed, and the platelets were resuspended in Tyrode's buffer, pH 7.2. After fixation, the cells were generally used within 24 hours but could be stored for 2 to 3 weeks at 4°C .

Platelet-binding assays. ^{125}I -TSP1-1 binding to platelets was measured as previously described³⁸ for the interaction of adhesive proteins with the cells. Typically, ^{125}I -TSP1-1 at 0.20 to 1.2 $\mu\text{mol}/\text{L}$ was incubated with washed human platelets at $1 \times 10^8/\text{mL}$ to $2 \times 10^9/\text{mL}$ in a final volume of 200 μL in Tyrode's-albumin buffer, pH 7.2. The platelets were then activated with thrombin at 0.25 U/mL. Following an incubation period at 22°C , triplicate 50- μL aliquots of the incubation mixture were layered onto 20% sucrose and centrifuged in a Beckman microfuge for 2.5 minutes. The tips of the tubes containing the platelets were amputated and counted. By means of the specific activity of the radiolabeled ligand, the number of antibody molecules bound per platelet was determined. Nonspecific binding, N_1 , as determined using the "Ligand" program,³⁹ ranged from 0 to $3 \times 10^{-2}\%$ of the TSP1-1 input concentration and was verified experimentally at low-input concentrations of ^{125}I -TSP1-1 in the presence of a large excess of nonlabeled antibody. All data presented represent specific binding of the antibody.

Immunoblotting analyses. Plasmin (KabiVitrum, Stockholm)

was added to human TSP to a final concentration of 0.5 U/mL with TSP at 1 mg/mL. The data shown in this study was obtained with a 3-hour digest at 37°C . The sample was added to an equal volume of Laemmli sample buffer³⁹ containing 2% 2-mercaptoethanol and was boiled. These samples were then subjected to PAGE in the buffer system of Laemmli,⁴⁰ using a 10% resolving gel with a 3.3% stacking gel. After electrophoresis, the protein was transferred from the gel to nitrocellulose for 1 hour at a constant current of 275 mA.⁴¹ Nonspecific binding to the nitrocellulose was reduced by incubation with a phosphate buffer containing casein⁴² for 1 hour at 22°C . TSP1-1 ascites fluid, at a dilution of 1:250 in the casein-blocking buffer, was added to the nitrocellulose and incubated for 2 hours. The nitrocellulose sheets were then washed three times, each time for 10 minutes with the same buffer. Immunochemically purified ^{125}I -radiolabeled anti-mouse IgG diluted in the phosphate-casein buffer (0.5 $\mu\text{g}/\text{mL}$) was added to the washed nitrocellulose sheets. Following a 2-hour incubation at 22°C , three 10-minute washes with the blocking buffer were performed; last, the sheets were washed with PBS. The bound radiolabeled anti-mouse IgG was detected by autoradiography of the dried sheets; mol wts were estimated from the mobilities of mol wt standard proteins applied to the gel.

RESULTS

Antibody specificity. TSP1-1 was specific for TSP based on the following criteria. The antibody reacted with TSP in a solid-phase radioimmunoassay, and this interaction could be inhibited by purified TSP in the fluid phase. In similar analyses, the antibody did not react with fibrinogen or fibronectin. In immunoblotting analyses, the antibody reacted with a single component in platelet lysates with the same mobility as purified TSP, and in immunofluorescence the antibody stained in a pattern consistent with α -granule localization.⁴³

To characterize further the recognition specificity of TSP1-1, purified TSP was subjected to plasmin digestion in the presence of Ca. The resulting samples were subjected to electrophoresis on 10% polyacrylamide gels under reducing conditions and then electrophoretically transferred onto nitrocellulose. The gel of nondigested TSP and the digest is shown in the left panel of Fig 1. Nondigested TSP (lane 1) exhibited a single, major band with an estimated mol wt of 180 kd, consistent with the properties of the TSP subunits in the Laemmli gel system.⁴⁴ The digest (lane 2) contained two major bands at estimated mol wts of 150 kd and 30 kd. Based on the studies of Lawler and Slater⁴⁵ the 30-kd fragment corresponds to the heparin binding fragment from the amino-terminal region of TSP. When the transfers were subjected to immunoblotting analyses with TSP1-1, the antibody reacted with the intact subunits of TSP (right panel, lane 3). In the plasmin digest (lane 4), TSP1-1 reacted with the 30-kd but not the 150-kd fragment of TSP. This suggests that the TSP1-1 epitope resides in the heparin binding domain of TSP.

Binding of TSP1-1 to platelets. TSP1-1 was radioiodinated and used to assess the availability of the recognized epitope on the surface of thrombin-stimulated and nonstimulated platelets. In the initial set of experiments, ^{125}I -TSP1-1 was used at an input concentration of 1 $\mu\text{mol}/\text{L}$ (determined by subsequent experiments to be a saturating dose of the antibody) with the cells at $2 \times 10^8/\text{mL}$. The data shown in

Fig 1. TSP was digested with 0.5 U plasmin per mg of TSP for 3 hours at 37 °C in the presence of 2 mmol/L of Ca. Both the intact protein and the digest were subjected to immunoblot analysis using TSP1-1 to determine which TSP domain contains the TSP1-1 epitope. Left panel, 10% Laemmli gel stained with Coomassie Blue: lane 1, intact TSP; lane 2, plasmin digest of TSP. Right panel, autoradiogram of the immunoblot with TSP1-1: lane 3, intact TSP; lane 4, plasmin digest of TSP. Arrow indicates peptide generated by plasmin cleavage. The contaminant in the starting sample in this mol wt range did not appear to be affected by the digestion with plasmin.

Table 1 were obtained after a 60-minute incubation and establish two major points regarding surface expression of TSP. First, surface expression of TSP is increased when the platelets are stimulated. In the presence of Ca + Mg, thrombin-stimulated platelets bound 15 times more TSP1-1 than did nonstimulated platelets in the presence of PGE1 and theophylline. In addition, when blood was drawn directly into PGE1 and theophylline and the inhibitors were maintained throughout the platelet isolation, TSP1-1 binding was further reduced. When ^{125} I-TSP1-1, at 0.3 μ mol/L, was incubated for 30 minutes with platelets prepared from blood drawn into PGE1 and theophylline, <200 antibody molecules were bound per platelet in the presence of EDTA or Ca + Mg as compared with 1,000 molecules bound per platelet when the inhibitors were added directly to the isolated cells. Second, thrombin-stimulated surface expression of TSP was detected in the presence of EDTA. The

Table 1. Surface Expression of TSP on Resting and Thrombin-Stimulated Platelets

Divalent Ion Condition	^{125} I-TSP1-1 Bound (Molecules/Platelet)	
	Resting	Stimulated
EDTA	850 $\pm$ 20	3,100 $\pm$ 500
Ca + Mg (2 mmol/L of each)	1,100 $\pm$ 340	16,000 $\pm$ 4,200

^{125} I-TSP1-1 was added at a saturating dose, 1 μ mol/L, to resting or thrombin-stimulated (0.25 U/mL) fresh platelets at 2×10^8 /mL, and binding was measured after 60 minutes. PGE1 and theophylline were present in the resting platelet preparation at 1 μ g/mL and 1 mmol/L, respectively.

extent of surface expression was reduced relative to that observed in the presence of Ca + Mg, but still constituted a significant increase, approximately fourfold, as compared with nonstimulated cells.

With these data suggesting that the divalent ions may regulate the extent of TSP surface expression, the divalent ion conditions for surface expression were further investigated. With ^{125} I-TSP1-1 added at its K_d (0.2 μ mol/L), thrombin-stimulated surface expression of TSP was measured in the presence of Ca + Mg, Ca or Mg, Mg-EGTA, or EDTA (Fig 2). In the absence of divalent ions (EDTA), or in the presence of Mg-EGTA or Ca, the binding of TSP1-1 was measurable but remained at a relatively low level with 3,000 to 3,500 molecules of antibody bound per platelet. Addition of Mg or Ca alone at concentrations as high as 3.8 or 4 mmol/L,⁴⁶ respectively, failed to augment TSP surface expression. When 2 mmol/L of Ca + 2 mmol/L of Mg were present, a fourfold increase (3,500 v 17,400 molecules of TSP1-1 per platelet) in TSP surface expression occurred. A similar increase in antibody binding was also observed with the addition of Mg without chelation of endogenous Ca, suggesting that the platelets may provide a sufficient quantity of this ion for maximal TSP surface expression.

TSP1-1 binding to thrombin-stimulated platelets reached steady state at similar times in the presence of Ca + Mg and EDTA. As shown in Fig 3, under both conditions, apparent equilibrium binding was observed in 60 minutes. At a single concentration of TSP1-1 (0.25 μ mol/L) as in Fig 3, increased binding could reflect an increase in the affinity of the antibody for TSP in the presence of Ca + Mg rather than reflect an increase in the quantity of TSP on the platelet surface. Therefore, the binding of TSP1-1 added at varying concentrations to thrombin-stimulated platelets was assessed

Fig 2. ^{125} I-TSP1-1 was incubated with thrombin-stimulated (0.25 U/mL) platelets at a platelet concentration of 2×10^8 /mL. The final concentration of EDTA was 5 mmol/L. The concentration of Mg + Ca ranged from 0.5 to 4 mmol/L and the concentration of Mg-EGTA ranged from 5 mmol/L of EGTA–1 mmol/L of Mg to 5 mmol/L of EGTA–4 mmol/L of Mg, at which point the calculated free Mg concentration was ~3.8 mmol/L.⁴⁷

Fig 3. Platelets were stimulated with thrombin (0.25 U/mL) for 10 minutes prior to fixation with paraformaldehyde. Following a wash of the platelets with Tyrode's buffer, ^{125}I -TSP1-1 (0.25 $\mu\text{mol/L}$) was added to the cells ($2 \times 10^8/\text{mL}$) for varying periods of incubation (5 to 90 minutes). Ca + Mg (2 mmol/L of each) present during stimulation (○), EDTA (5 mmol/L) present during stimulation (●).

under various divalent ion conditions. In these experiments, both fresh and paraformaldehyde-fixed washed platelets were used. The affinity of TSP1-1 for platelet-bound TSP may be different than that for TSP in solution, and the free TSP may compete with a high affinity for TSP1-1 binding, resulting in an underestimation of the affinity of TSP1-1 for platelet-bound TSP. Therefore, platelets were stimulated, fixed with paraformaldehyde, and then washed to remove free TSP prior to the assay. Binding isotherms were constructed by adding increasing concentrations of ^{125}I -TSP1-1 (0.2 to 1.2 $\mu\text{mol/L}$) to thrombin-stimulated fixed or nonfixed platelets at $2 \times 10^8/\text{mL}$. The results shown in Fig 4 were obtained in the presence of EDTA, and saturation of antibody binding is apparent for both the fresh and fixed platelets. Such data were subjected to Scatchard analyses, and the binding parameters derived are summarized in Table 2. The affinity of TSP1-1 for platelet-bound TSP showed little variation with divalent ion conditions; however, the number of TSP1-1 binding sites was greater than eightfold higher in the presence of Ca + Mg as compared with EDTA. The slight shift in affinity of the antibody for fixed platelets as compared with fresh platelets suggests that the antibody does not have a significantly higher affinity for TSP in solution than for platelet-bound TSP.

The ability of EDTA to reverse the Ca + Mg-dependent surface expression of TSP on thrombin-stimulated platelets was also investigated (Table 3). Cells were activated with thrombin for 10 minutes in the presence of Ca + Mg, a condition that induced a full secretory response as measured by β -thromboglobulin release. EDTA was then added to a final concentration of 10 mmol/L. With an input concentration of ^{125}I -TSP1-1 of 1.0 $\mu\text{mol/L}$, EDTA reduced binding of the antibody to platelets by ~65% as compared with that observed in the presence of Ca + Mg, and this reduction approached the level of surface expression noted on cells activated in the presence of EDTA. These results indicate that EDTA can reverse the increased TSP surface expression that occurs in the presence of Ca + Mg. This reversal was

Fig 4. Increasing concentrations of ^{125}I -TSP1-1 (0.2 to 1.2 $\mu\text{mol/L}$) were incubated with either fresh or paraformaldehyde-fixed platelets. The fresh cells were stimulated with thrombin (0.25 U/mL) at a cell concentration of $4 \times 10^8/\text{mL}$ prior to the assay. To prepare the fixed cells, platelets were stimulated with thrombin (0.25 U/mL) at a cell concentration of $1.5 \times 10^9/\text{mL}$ and fixed with 0.05% paraformaldehyde and then washed with Tyrode's buffer to remove free TSP. Both sets of cells were diluted to a final concentration of $2 \times 10^8/\text{mL}$ in the binding assay.

also observed with γ -thrombin as the stimulus of platelet secretion (Table 3).

TSP may become surface expressed through its secretion into the extracellular milieu and its subsequent binding to the cell surface. Accordingly, platelet concentration at the time of thrombin stimulation would determine the concentration of TSP available for binding the cells; therefore, the extent of TSP surface expression would be dependent on platelet concentration. This prediction has been examined experimentally. Platelets, at concentrations from $1 \times 10^8/\text{mL}$ to $2 \times 10^9/\text{mL}$, were stimulated with thrombin in the presence of either Ca + Mg or EDTA and then fixed with paraformaldehyde. The cell concentration was then adjusted to $2 \times 10^8/\text{mL}$, and surface expression of TSP was measured using a saturating dose of TSP1-1 (1.1 $\mu\text{mol/L}$) as a probe. The results are summarized in Table 4. The TSP surface expression increased sixfold and was 90% divalent ion dependent at the highest cell concentration tested ($2 \times 10^9/\text{mL}$). Thus, as the platelet concentration at the time of thrombin stimulation increased, resulting in higher concentrations of secreted TSP, TSP surface expression also increased in the presence of Ca + Mg. This effect was not noted in the presence of EDTA. Surface expression varied by only 14% at the lowest and highest platelet concentrations used in the presence of EDTA as compared with a >700% difference in the presence of Ca + Mg.

DISCUSSION

TSP1-1 recognizes an epitope in the heparin-binding domain of TSP. Because this antibody has been previously shown to inhibit the lectinlike activity of TSP,³⁰ this localization suggests that the amino-terminal region of the molecule is involved in this function, consistent with the data of other researchers,⁴⁷ and that this region is available on the platelet surface in the presence or absence of divalent ions. Using TSP1-1 to measure surface expression of the molecule, we

Table 2. Summary of TSP1-1 Binding Parameters

Parameter	Platelets			
	Fresh		Fixed	
	Ca + Mg	EDTA	Ca + Mg	EDTA
Dissociation constant K_d (nmol/L)	165 $\pm$ 55	540 $\pm$ 220	200 $\pm$ 70	90 $\pm$ 80
Binding sites (TSP1-1 molecules/platelet)	17,000 $\pm$ 2,000	5,200 $\pm$ 1,300	42,000 $\pm$ 9,000	5,000 $\pm$ 1,500

Varying concentrations of ^{125}I -TSP1-1 were added to platelets at $2 \times 10^8/\text{mL}$ in the presence of Ca + Mg (2 mmol/L of each) or EDTA (5 mmol/L). The fresh platelets were stimulated with thrombin (0.25 U/mL) at a concentration of $4 \times 10^8/\text{mL}$ and diluted to $2 \times 10^8/\text{mL}$ in the assay, whereas the paraformaldehyde-fixed platelets were stimulated with thrombin (0.25 U/mL) prior to fixation at a concentration of $1.5 \times 10^8/\text{mL}$ and diluted to $2 \times 10^8/\text{mL}$ in the assay.

found that maximal exposure of TSP on thrombin-stimulated platelets requires the presence of both Ca + Mg. In the presence of Ca alone, EDTA or Mg-EGTA surface expression was reduced relative to the Ca + Mg condition. Mg alone, but not Mg-EGTA, was as effective as Ca + Mg in supporting TSP surface expression, suggesting that the endogenous pool of Ca supplied by the platelets is a sufficient source of this ion for optimal TSP exposure.

The enhanced TSP1-1 binding in the presence of Ca + Mg could be an effect of the combination of divalent ions on the affinity of TSP1-1 for the molecule, or on platelet secretion, which would control the availability of TSP, or directly on the quantitative expression of TSP on the platelet surface. The affinity of TSP1-1 for the molecule on the platelet surface in the presence of Ca + Mg or EDTA was quite similar. Using purified TSP in a fluid-phase radioimmunoassay or in a solid-phase radioimmunoassay with TSP coupled to plastic microtiter wells, we found that TSP1-1 binding also was similar under varying divalent ion conditions (unpublished observations, August 1985). Moreover, the affinity of TSP1-1 for platelets in the presence or absence of Ca + Mg did not vary significantly when measured with either fresh or fixed platelets. Therefore, differences in the affinity of TSP1-1 for TSP in the presence of Ca + Mg as contrasted to other divalent ion conditions does not appear to be the basis for its increased binding. That Ca + Mg enhances platelet secretion of TSP also appears to be excluded. When platelets were stimulated in the presence of Ca + Mg and then EDTA was added, TSP1-1 binding was reduced and approached the levels that occurred when cells were stimulated in the presence of EDTA. Thus, it

seems likely that Ca + Mg directly increases the number of TSP molecules, or more precisely the number of TSP1-1 epitopes, on the surface of thrombin-stimulated platelets. It is well established that TSP is a Ca-binding protein and that the removal of Ca results in a conformational change of the molecule.⁴⁴ Whether Mg has an additional effect on the molecule, the platelet, or both remains to be demonstrated. It is noteworthy in this regard that Dixit and colleagues¹² reported that the association of TSP and fibrinogen is also optimal in the presence of both divalent ions, and a preliminary report⁴⁸ also suggests that TSP binding to macrophages is optimal in the presence of both divalent ions.

Removal of all divalent ions with EDTA did not entirely abolish TSP surface expression. This result suggests that existence of at least two distinct mechanisms for surface expression of TSP. One pathway is divalent ion independent, and the second is dependent on Ca + Mg. The relative contribution of these two pathways to TSP surface expression is dependent on platelet concentration. When platelets were stimulated at a low cell concentration ($1 \times 10^8/\text{mL}$), ~60% of the TSP surface expression was divalent ion independent. As the cell concentration was increased, the quantity of TSP surface expressed by the divalent ion-independent mechanism remained relatively constant, whereas the Ca + Mg-dependent surface expression increased until it constituted ~90% of the TSP surface expression at the highest platelet concentration tested ($2 \times 10^9/\text{mL}$). The

Table 3. Effect of EDTA on TSP Surface Expression

Ion Condition	(TSP1-1 Molecules/Platelet)	
	γ -Thrombin (10 U/mL)	α -Thrombin (0.25 U/mL)
Ca + Mg (2 mmol/L of each)	17,000	19,000
EDTA* (10 mmol/L)	3,100	4,300
EDTA† (10 mmol/L)	6,300	6,100

^{125}I -TSP1-1 (1.0 $\mu\text{mol/L}$) was added to stimulated, fresh platelets at $2 \times 10^8/\text{mL}$ in the presence of Ca + Mg or EDTA. In one set of samples, the platelets were stimulated in the presence of Ca + Mg with the addition of EDTA after a 10-minute incubation.

*EDTA present at time of stimulation.

†EDTA added after the cells were incubated with the stimulus for 10 minutes in the presence of Ca + Mg.

Table 4. Effect of Cell Concentration on TSP Surface Expression

Platelets* (Cells/mL)	TSP1-1 Bound (Molecules/Platelet)		
	Ca + Mg (2 mmol/L of each)	Total† (%)	EDTA (5 mmol/L)
1×10^8	7,100	40	4,300
5×10^8	22,000	86	3,200
1×10^9	36,300	85	5,600
2×10^9	60,000	92	5,000

Platelets at varying concentrations were stimulated with thrombin (0.25 U/mL) for 10 minutes prior to fixation with paraformaldehyde. The fixed cells were then centrifuged and resuspended in Tyrode's buffer at a final cell concentration of $2 \times 10^8/\text{mL}$ in the assay. The cells were incubated with ^{125}I -TSP1-1 (1.1 $\mu\text{mol/L}$) for 60 minutes.

*Platelet concentration at the time of stimulation.

†If it is assumed that TSP1-1 binding in the presence of Ca + Mg represents the sum of divalent ion-dependent and -independent binding or 100% of the total TSP surface expression, this is the percentage attributable to a divalent ion-dependent mechanism.

existence of these two independent pathways may reconcile previous data^{26,27} regarding the divalent ion dependence of TSP surface expression. From our data, it is clear that both mechanisms can occur and that platelet concentration can be an important variable in determining the relative contribution of each mechanism. The basis for the effect of platelet concentration remains to be established. The most direct explanation is that platelet concentration at the time of thrombin stimulation determines the concentration of available TSP in solution. At 10^8 or 10^9 platelets/mL the theoretical concentration of secreted TSP would be 4 or 40 nmol/L, respectively.⁴⁹ If the divalent ion-independent mechanism is of high affinity and low capacity such that these sites are saturated at 4 nmol/L of TSP, an increase in the TSP concentration would not increase the number of molecules bound per platelet. In contrast, if the Ca + Mg-dependent reaction is of lower affinity and higher capacity, a tenfold increase in available TSP concentration could increase surface expression significantly. As noted below, this interpretation is consistent with our previous data³¹ on the binding of exogenously added TSP to platelets. More complex explanations, however, cannot be excluded. For example, the concentration of other secreted platelet constituents could also influence TSP binding to platelets, or the state of TSP polymerization⁵⁰ could be influenced by Ca + Mg.

We recently showed that the binding of exogenously added TSP to platelets also involves two distinct mechanisms.³¹ One of these mechanisms is divalent ion dependent. It occurs with relatively low affinity ($K_d = 250$ nmol/L) and high capacity ($35,600 \pm 9,600$ sites per cell). The divalent ion-independent mechanism for binding of exogenously added TSP is of higher affinity ($K_d = 50$ nmol/L) and lower capacity ($3,100 \pm 1,000$ sites per platelet). Thus, the predictions regarding the relative affinity and capacity of the divalent ion-independent and the Ca + Mg-dependent mechanism of

surface expression are consistent with the binding of exogenously added TSP. The data from the two studies are not entirely in agreement. First, the divalent ion-dependent binding of exogenous TSP could be demonstrated in the presence of Ca or Mg alone. Second, since the divalent ion-independent surface expression of TSP changed minimally with platelet concentration, a very high-affinity interaction, higher than a K_d of 50 nmol/L, is predicted. If endogenous and exogenous TSP bind to the same receptors, when exogenous TSP is added it must compete with secreted endogenous TSP for binding sites, which would result in a lower apparent affinity for TSP binding. Thus, the difference in affinity of exogenous TSP for the divalent ion-independent binding site ($K_d = 50$ nmol/L) and the affinity of endogenous TSP for the platelet surface in the presence of EDTA (apparent $K_d < 4$ nmol/L based on estimated available TSP concentrations) may be artifactual. It is also possible that the differences found between the binding of exogenous TSP and the surface expression of endogenous TSP is due to subtle changes arising during purification of the molecule.

When blood was collected into PGE1 and theophylline and these inhibitors were maintained throughout the platelet isolation, <200 molecules of TSP1-1 bound per platelet. Based on the affinity and the plasma concentration of TSP, it is predicted that <250 molecules of TSP should be present on the surface of nonstimulated platelets. The practical implications of these results is that detection of TSP on the platelet surface with monoclonal antibodies such as TSP1-1 could prove to be a useful marker for platelet activation. Extensive and detailed investigations will be necessary to assess this possibility.

ACKNOWLEDGMENT

We thank Sandra M. Peterson for production of TSP1-1 ascites and Judy Taylor for preparing the manuscript.

Preclinical Assessment of Purging With VP-16-213: Key Role for Long-Term Marrow Cultures

By Brian H. Kushner, Jong-Hyo Kwon, Subhash C. Gulati, and Hugo Castro-Malaspina

An evaluation of the effects of VP-16 on normal human marrow cells and representative lymphoma-leukemia cell lines was performed to assess this agent's applicability to ex vivo marrow purging. Tumoricidal dose curves were defined using malignant lymphoid (SK-DHL2 and Reh) and myeloid (HL-60) cells admixed with a 20-fold excess of irradiated marrow cells to simulate a borderline remission marrow. One-hour treatments yielded ID_{50} of $<5 \mu\text{mol/L}$ of VP-16 for clonogenic units from each cell line; rare-to-zero clonogenic units survived exposure to 50 to 100 $\mu\text{mol/L}$. CFU-Mix, BFU-E, and CFU-GM were equal in their sensitivity to VP-16 (ID_{50} s 25 to 30 $\mu\text{mol/L}$). Marrows treated with 75 $\mu\text{mol/L}$ were completely depleted of these colony-forming cells but produced CFU-GM in one-stage long-term

marrow cultures (LTMCs). This dose had little adverse effect on the proliferative capacity of marrow stromal progenitors, as measured by CFU-F (ID_{50} 271 $\mu\text{mol/L}$) and by the unperturbed development of adherent layers in LTMCs. Furthermore, these stromal layers were able to support hematopoiesis as well as controls in co-culture experiments with autologous marrow cells (two-stage LTMCs). In conclusion, doses of VP-16 that cleanse marrow of lymphoma-leukemia cells spare hematopoietic and stromal progenitors as demonstrated by LTMCs. These data favor the use of VP-16 in the clinical autotransplant setting.

© 1987 by Grune & Stratton, Inc.

THE FEASIBILITY of eliminating neoplastic cells from harvested bone marrow¹ has spurred the use of myeloablative chemoradiotherapy with autologous marrow rescue. Immunologic²⁻⁴ or pharmacologic^{1,5,6} manipulations exploit differential features or sensitivities of malignant cells to maximize antineoplastic impact while preserving hematopoietic stem cells needed for hematologic recovery post-transplant. Noxious effects on marrow stromal cells in the autograft pose an additional concern.⁷ The intravenous transplantability of these cells and the replacement of host stroma by cells of donor origin remain unsettled points⁸⁻¹⁰ but may prove to be key issues if evolving myeloablative regimens are found to impair the marrow microenvironment's hematopoietic supportive functions.^{11,12}

Purging methods differ in terms of these objectives. For example, although monoclonal reagents and complement spare normal hematopoietic and stromal cells, their antineoplastic effect may be blunted by excess marrow.^{2,7,13} Conversely, chemopurification reliably eliminates tumor cells despite excess marrow, but it also depletes hematopoietic^{6,14,15} and, to a lesser degree, marrow stromal progenitors.¹⁴

VP-16-213 (VP-16), an active anti-lymphoma/leukemia derivative of podophyllotoxin, arrests cells in late S or early G₂ phase.^{16,17} A linear relation between VP-16 dosage and greater antineoplastic effect,¹⁸ plus its in vitro activity, make VP-16 an attractive candidate for marrow purging. To explore this potential, we correlated the effects of VP-16 on the hematopoietic and stromal compartments of human bone marrow with its toxicity on representative lymphoma-leukemia cell lines. The studies support a role for VP-16 in purging and highlight the usefulness of long-term marrow cultures (LTMCs) for preclinical assessments of purging regimens.

MATERIALS AND METHODS

Cells and Incubation Procedure

Heparinized bone marrow aspirates from the iliac crests of healthy volunteers who gave informed written consent were centrifuged at 200 g for 10 minutes. Buffy coat cells were then suspended in α -medium (Flow Laboratories, Hamden, CT) with 10% heat-inactivated fetal calf serum (FCS).

Neoplastic targets included: (a) SK-DHL2, a B cell lymphoma line with an 8;14 translocation¹⁹; (b) a common ALL antigen

(CALLA+), non-T, non-B acute lymphoblastic leukemia cell line²⁰; and (c) HL-60, a promyelocytic leukemia cell line.²¹ Cells were kept at 37 °C in a humidified 5% CO₂ atmosphere and were maintained in exponential growth in RPMI 1640 (GIBCO, Grand Island, NY) with 10% FCS, 1% penicillin:streptomycin:neomycin (PSN), and 1% glutamine (GIBCO).

VP-16 (Bristol, Syracuse, NY) was diluted with calcium- and magnesium-free phosphate-buffered saline (PBS) immediately before use. Marrow buffy coat cells at 5 or 20 $\times 10^6/\text{mL}$ of α -medium with 10% FCS, and neoplastic cells (alone or admixed with a 20-fold excess of irradiated [4,000 rad] marrow cells) at 1 $\times 10^6/\text{mL}$ of RPMI 1640 with 10% FCS, were incubated at 37 °C for 1 hour with graded doses of VP-16 or medium control, washed three times and collected for use.

Culture Techniques

Lymphoma-leukemia colony-forming cells. Because of preliminary studies that showed suboptimal colony size and reduced plating efficiency when treated neoplastic cells were cultured at more than 10⁵/mL, 200 and 10³ untreated or 10³ and 10⁴ treated lymphoma-leukemia cells in 1 mL of culture medium were plated in quadruplicate onto 1-mL underlayers prepared in 35-mm dishes (Lux Scientific Co, Newburg, CA). The culture medium consisted of 1.08% methylcellulose in RPMI 1640 with 20% FCS, 1% PSN, and 1% glutamine; the underlayers consisted of 0.5% agar in McCoy's 5A medium with 20% FCS and 1% PSN, but no feeder cells. Cultures were incubated at 37 °C in a humidified 5% CO₂.

atmosphere and scored for colonies (>50 cells/aggregate) on day 10.

Granulocyte-macrophage colony-forming cells. Control or VP-16-treated marrow buffy coat cells were cultured as described¹⁴ in quadruplicate in 35-mm dishes (Corning Glass Works, Corning, NY) at 2×10^5 /mL of 0.3% agar in supplemented McCoy's 5A medium and 10% FCS; in each dish, 0.1 mL of medium conditioned by the 5637 bladder carcinoma cell line stimulated colony formation.²² CFU-GM (>50 cells/aggregate) were scored on day 7.

Multilineage and erythroid colony-forming cells. Mononuclear cells were recovered from control and VP-16-treated marrow buffy coat cells by neutral density centrifugation in an isotonic sterile Percoll solution (1.074 g/mL, 270 mOsm) (Pharmacia, Piscataway, NJ) and were cultured, as described,²³ in quadruplicate in 35-mm dishes (Lux) at 0.5 to 1.0×10^5 /mL of 1% methylcellulose in Iscove's modified Dulbecco's medium (IMDM) with 30% human plasma, 10% phytohemagglutinin-stimulated leukocyte-conditioned medium, 5×10^{-5} mol/L of 2-mercaptoethanol, and 1 U of human recombinant erythropoietin (AMGen, Thousand Oaks, CA). CFU-Mix and BFU-E were scored on day 14. Random colonies were plucked and stained with Wright-Giemsa solution for verification of cellular composition.

CFU-GM generation in one-stage LTMCs. Twenty $\times 10^6$ control or VP-16-treated marrow buffy coat cells suspended in 10 mL of medium were inoculated into T-25 flasks (Corning) which were gassed with 5% CO₂ in air, and kept at 33 °C. The LTMC medium consisted of supplemented McCoy's 5A medium,¹⁴ 12.5% horse serum, 12.5% FCS, and 10^{-6} mol/L of hydrocortisone sodium succinate. On day 5, supernatants were purged of erythrocytes and mature myeloid cells by Percoll separation; the mononuclear cells were returned to their flasks in fresh medium. Half of the supernatant was removed weekly and the cells in suspension were assayed for CFU-GM. At week 7, adherent layers were suspended, as described,¹⁴ using a nontoxic 0.01% (wt/vol) Ca²⁺-free and Mg²⁺-free trypsin (GIBCO) solution to determine their CFU-Mix, BFU-E, and CFU-GM content.

Fibroblast colony-forming cells. Five $\times 10^6$ control or VP-16-treated marrow buffy coat cells in 20-mL of α -medium with 20% FCS were set up in T-75 flasks (Corning), which were gassed with 5% CO₂ in air and kept at 37 °C. Medium was renewed on day 4. Cultures were stopped on day 10, stained with Wright-Giemsa solution, and scored for CFU-F (>50 cells/aggregate).²⁴

Stromal layers in LTMCs. To monitor the kinetics of stromal layer development, the extent of flask coverage by an interlocking network of cells was estimated weekly by phase microscopy. Cellular composition was assessed *in situ* by immunofluorescence methods as described.¹⁴ Fibroblasts were identified by rabbit antibodies to fibronectin (Bethesda Research Laboratory, Gaithersburg, MD) and to type III collagen (kindly provided by Dr H. Furthmayr, Yale University). Endothelial cells and macrophages were identified by mouse monoclonal antibodies (Australian Monoclonal Development, Antammon, Australia) to factor VIII-related protein and to human monocytes/macrophages, respectively. Lipid-containing cells were distinguished by their morphology.

To assess the hematopoietic supportive capacity of stromal layers established from VP-16-treated marrow, all suspension cells were removed from 5-week-old LTMCs and 15×10^6 freshly isolated nonadherent light-density (NAL) autologous marrow cells were added. NAL cells were obtained by Percoll separation followed by 12-hour adherence in T-75 flasks. The two-stage LTMCs were demopulated weekly for determination of CFU-GM content. Controls included: (a) cell-free LTMC medium on stromal layers from untreated and VP-16-treated marrow, (b) NAL cells in LTMC medium without stromal layers, and (c) NAL cells on stromal layers from untreated marrow.

RESULTS

Effect of VP-16 on Clonogenic Lymphoma-Leukemia Cells

VP-16 exerted a dose-dependent killing of clonogenic lymphoma-leukemia cells (Fig 1). In the absence or presence of a 20-fold excess of irradiated marrow cells during the 1-hour incubation period, the dose of VP-16 that inhibited 50% (ID₅₀) and 90% (ID₉₀) of colony growth for all three cell lines was <5 μ mol/L and <10 μ mol/L, respectively. Rare-to-zero clonogenic SK-DHL2 and Reh cells survived treatments with 50 to 100 μ mol/L of VP-16; these doses eliminated all clonogenic HL-60 cells.

Effect of VP-16 on Hematopoietic Colony-Forming Cells

Recovery of hematopoietic progenitors was dose and cell concentration dependent. When marrow buffy coat cells

Fig 1. Comparison of the effect of VP-16 on lymphoma-leukemia cells (A) and hematopoietic progenitor cells (B). Mixtures containing 1×10^6 neoplastic cells and 2×10^6 irradiated marrow cells per milliliter were incubated with VP-16, washed, and plated for clonogenic units. Results shown are the mean of four experiments for each cell line. Controls (mean $\pm$ SEM) were: SK-DHL2, 1713 ± 554 ; Reh, 2272 ± 646 ; HL-60, 2172 ± 697 . In separate studies, normal marrow at 20×10^6 cells/mL was incubated with VP-16, washed, and assayed for colony-forming cells. Results shown are the mean (SEM $< \pm 6\%$) of four (CFU-Mix, BFU-E) and six (CFU-GM) experiments. Controls were: CFU-Mix, 10 ± 2 ; BFU-E, 69 ± 6 ; and CFU-GM, 101 ± 11 . Note the greater sensitivity to VP-16 of neoplastic cells (ID₅₀s $< 5 \mu$ mol/L) v normal hematopoietic progenitors (ID₅₀s 25 to 30 μ mol/L), and the similarity in dose-response curves of CFU-Mix, BFU-E, and CFU-GM.

*Marrow buffy coat cells were treated at 20×10^6 /mL with 50 μ mol/L of VP-16 for 1 hour.

†Low-density mononuclear marrow cells.

‡Marrow buffy coat cells.

were treated at 20×10^6 /mL, ID_{50} s of the growth of CFU-Mix, BFU-E, and CFU-GM were 25 to 30 μ mol/L of VP-16, and colony growth was completely abolished by 75 μ mol/L (Fig 1). In contrast, after treatment at the lower cell concentration of 5×10^6 /mL, the ID_{50} of CFU-GM was 12.5 μ mol/L, and all colony growth was inhibited by 50 μ mol/L (data not shown).

To rule out drug carryover into the culture medium or an accessory cell phenomenon, VP-16-treated marrow cells were mixed at different ratios with untreated controls and plated for CFU-Mix, BFU-E, and CFU-GM. The observed numbers of colonies were within the range expected (Table 1).

CFU-GM Production in One-Stage LTMCs

The marrow cell concentration during incubation with VP-16 significantly affected the CFU-GM production in LTMCs. LTMCs derived from marrow suspensions treated with 75 and 50 μ mol/L at 20×10^6 and 5×10^6 cells/mL, respectively—and therefore containing no CFU-Mix, BFU-E, or CFU-GM as measured by direct assay in semisolid medium—generated CFU-GM for 4 to 7 weeks (Fig 2). No progenitors were detected in either the adherent or the nonadherent fractions of LTMCs established from marrow exposed to 100 μ mol/L of VP-16.

CFU-GM production in one-stage LTMCs established from control and VP-16-treated marrow is summarized in Table 2. Mean cumulative 5-week CFU-GM yields from

LTMCs initiated with marrow incubated at 20×10^6 cells/mL and treated with 25, 50, and 75 μ mol/L of VP-16 were 60%, 18%, and 3%, respectively, of controls. Cumulative 5-week CFU-GM yields after treatments with 0, 25, 50, and 75 μ mol/L were, respectively, 127%, 153%, 290%, and a much higher but indeterminate percentage of the CFU-GM content present at the time of LTMC initiation.

LTMCs derived from marrow incubated with 25 and 50 μ mol/L of VP-16 at 5×10^6 cells/mL produced mean cumulative 5-week CFU-GM yields of 42% and 3%, respectively, of controls (Table 2). Treatments at 5×10^6 cells/mL with 0, 25, and 50 μ mol/L resulted in LTMC cumulative 5-week CFU-GM yields that were 114%, 251%, and again a higher but indeterminate percentage of the respective CFU-GM numbers of the initiating inocula.

Effect of VP-16 on Marrow Stromal Cell Proliferative Capacity

CFU-F inhibition by VP-16 was dose and cell concentration dependent (Fig 3). Increasing doses of VP-16 caused an exponential decrease in CFU-F recovery. Treatments at a high cell concentration produced less cytotoxicity: ID_{50} s of CFU-F growth were 271 and 180 μ mol/L of VP-16 after incubations at 20×10^6 cells/mL and 5×10^6 cells/mL, respectively.

Marrow treated with up to 75 μ mol/L of VP-16 and then inoculated for LTMCs gave rise to confluent stromal layers at a rate comparable to that of untreated marrow, ie, within 3

Fig 2. CFU-GM production in one-stage long-term marrow cultures (LTMCs) derived from control and VP-16-treated marrow. In these representative experiments, no corrections were made for weekly demipopulations. Note the prolonged recovery of CFU-GM from LTMCs established with marrow which at the time of LTMC initiation contained no directly measurable hematopoietic progenitors.

Yield as percentage of CFU-GM inoculum	114%	251%	— *	0%

Mean $\pm$ SEM of four separate experiments at each treatment cell concentration. No corrections were made for weekly demipopulations. No CFU-GM were detected in cultures derived from marrow treated with 100 $\mu\text{mol/L}$ of VP-16 (data not shown).

*Because the denominator is zero, an exact figure cannot be affixed here.

to 4 weeks, and, as determined by immunofluorescence methods, contained fibroblasts, lipid-containing cells, and macrophages, with rare endothelial cells. Treatments with ≥ 100 $\mu\text{mol/L}$ of VP-16 delayed the attainment of confluence (Fig 4).

Fig 3. Survival curves for CFU-F after treatment with VP-16. Results shown are the mean $\pm$ SEM of five experiments at each cell concentration. The control CFU-F was 123 $\pm$ 9.

Functional Evaluation of Stromal Layers: CFU-GM Recovery From Two-Stage LTMCs

To evaluate their capacity to support hematopoiesis, confluent stromal layers were co-cultured with an autologous hematopoietic-cell-enriched marrow inoculum (NAL cells). CFU-GM recovery was comparable in two-stage LTMCs containing stromal layers derived from untreated and treated (up to 100 $\mu\text{mol/L}$ of VP-16) marrow and was greater and more prolonged than that noted when NAL cells were cultured as controls in flasks lacking stromal layers (Fig 5). CFU-GM were not detected in LTMCs to which NAL cells were not added.

DISCUSSION

Data presented herein delineate a differential sensitivity to VP-16 of normal marrow cells as compared with neoplastic cells and therefore support a role for VP-16 in marrow purging. Tumoricidal doses were defined using representative malignant lymphoid and myeloid cell lines. Neoplastic cells were treated alone or admixed with irradiated marrow cells in a simulated borderline remission situation. Treatments with 50 to 100 $\mu\text{mol/L}$ of VP-16 eliminated clonogenic malignant cells in the presence or absence of excess marrow.

After incubation of normal marrow with these doses, CFU-Mix, BFU-E, and CFU-GM were undetectable by direct assay in semisolid medium. Experiments mixing untreated and treated marrow made an accessory cell phe-

Fig 4. Kinetics of stromal layer development in long-term marrow cultures derived from control and VP-16-treated marrow. Results shown are the mean of five experiments. Stromal layers established from marrow incubated with 250 to 500 $\mu\text{mol/L}$ of VP-16 were devoid of macrophages and endothelial cells but eventually attained confluence due to proliferation of fibroblasts and lipid-containing cells.

nomenon an unlikely cause for the dose-dependent depletion of these progenitors. Colony assays have, however, been largely discredited as predictive of hematopoietic reconstitution capacity, since infusion of chemopurified marrow containing no detectable CFU-GM produces hematologic recovery in transplant patients pretreated with myeloablative chemoradiotherapy.⁶

LTCs provide an alternate means for studying hematopoietic progenitors in vitro.^{7,25-27} Increasing doses of VP-16 resulted in progressively greater LTC cumulative CFU-GM yields relative to the CFU-GM numbers present at culture initiation. Moreover, prolonged generation of CFU-GM occurred in LTCs established from marrow exposed to doses of VP-16 that abolish CFU-Mix, BFU-E, and CFU-GM in direct assays. These findings may reflect the survival of a pre-CFU-Mix population resistant to doses of VP-16 that are toxic to more mature progenitors. This interpretation presents the LTC system as a sensitive indicator of early hematopoietic precursor cell viability, as previously suggested by experiments in which marrow depleted of CFU-GM and BFU-E by complement and anti-Ia antibody generated these progenitors in LTCs.^{7,25,27} Alternatively, specific features of

the LTC system—for example, the presence of metabolically active stromal cells, or an extended time-frame that allows the repair of nonlethally injured cells or the recruitment of noncycling progenitors²⁸—may account for the detection of CFU-GM that go unidentified in semisolid medium assays. Either interpretation makes the LTC system a valuable tool for estimating hematopoietic cell survival in an ex vivo chemo-manipulated marrow.

Only very high concentrations of VP-16 (ie, 100 to 500 $\mu\text{mol/L}$) retarded the development and affected the composition of LTC adherent layers which normally contain cell types,²⁹ such as fibroblasts, lipid-containing cells, macrophages, and endothelial cells, that resemble those found in marrow studied in situ.¹¹ The largely fibroblastic nature of adherent layers derived from marrow treated with these doses of VP-16 reflects a resilience of CFU-F (ID_{50} 271 $\mu\text{mol/L}$), progenitors of the quantitatively predominant marrow stromal cell, that contrasts with hematopoietic progenitors (ID_{50} 25 $\mu\text{mol/L}$) and with clonogenic lymphoma-leukemia cells (ID_{50} <5 $\mu\text{mol/L}$). The heterogeneous adherent layers in LTCs derived from untreated marrow may be viewed as a model for the in vivo marrow microenvironment

Fig 5. Hematopoietic supportive capacity of long-term marrow culture stromal layers derived from control and VP-16-treated marrow. In this representative experiment, stromal layers were seeded with NAL cells containing 16.5×10^3 CFU-GM. VP-16-treated marrow gave rise to stromal layers that sustained hematopoietic cells as well as controls. Note the sharper decline in CFU-GM in the absence of stromal layers.

because, in addition to a compositional similarity, these layers demonstrate a hematopoietic supportive capacity.²⁵ VP-16 in doses up to 100 $\mu\text{mol/L}$ did not impair this functional property, as tested in the two-stage LTMC system which showed that stromal layers established from VP-16-treated marrow can sustain hematopoietic cells as well as controls.

Although data from LTMCs encourage purging possibly contaminated marrow with doses of VP-16 higher than those defined as safe by standard myeloid progenitor cell assays, the adequacy of the antineoplastic effect of these higher doses (ie, 50 to 75 $\mu\text{mol/L}$) remains problematical. Extrapolation to the actual autotransplant setting of data generated

with cell lines requires caution since the homogeneity and the high proliferative state of the neoplastic cells, plus their lack of prior exposure to chemotherapeutic agents, promote peak tumoricidal effect. However, the greater tumor burden in the borderline remission marrow model as compared with that aimed for clinically also deserves emphasis. Resolution of this issue, as well as certitude that these doses of VP-16 are sufficiently sparing of the pluripotent stem cell compartment so as not to jeopardize posttransplant hematologic recovery, await clinical correlations. Until these points are settled, the efficacy of VP-16 against lymphoma-leukemia cells *ex vivo* might best be exploited in combination with other drugs³⁰⁻³² or with immunologically mediated purging mechanisms.³³

Induction of NK Activity in Large Granular Lymphocyte Leukemia: Activation With Anti-CD3 Monoclonal Antibody and Interleukin 2

By Thomas P. Loughran, Jr, Kevin E. Draves, Gordon Starkebaum, Pamela Kidd, and Edward A. Clark

Large granular lymphocyte (LGL) leukemia is a rare disease characterized by clonal expansion of LGL associated with chronic neutropenia, multiple auto-antibodies, and occasionally polyarthritis. We studied cell surface antigen expression and functional activity of leukemic LGL from ten such patients. Using two-color flow cytometric analysis, we found that leukemic LGL from all ten patients expressed the CD3 and HNK-1 markers, while cells from only four patients expressed IgG Fc receptors (FcR). The LGL leukemic cells had little or no NK activity (defined as MHC-nonrestricted cytotoxicity against K562 target cells); however, NK activity could be induced in leukemic LGL by in vitro treatment with as little as 0.05 $\mu\text{g}/\text{mL}$ of anti-CD3 monoclonal antibody. Cell sorting experiments demon-

strated that NK activity was induced in CD3+ leukemic LGL (either CD3+, HNK-1+ or CD3+, FcR+) with anti-CD3 monoclonal antibody but not in normal CD3+, FcR- T cells. Treatment with purified interleukin 2 (IL 2) also caused direct activation of some CD3+ leukemic LGL. Despite induction with anti-CD3 MAb or IL 2, activated leukemic LGL did not proliferate or express high density IL 2 receptors detectable by cell sorter analysis. Treatment with alpha interferon had minimal effect on NK activity of LGL leukemic cells. These results suggest that leukemic LGL may provide a useful model for examining the signals required for LGL maturation and activation.

A SYNDROME of chronic neutropenia associated with increased numbers of large granular lymphocytes (LGL) has been identified recently.¹ In some of these patients this disease results from a clonal expansion of LGL that is clinically associated with a variety of autoimmune phenomena.^{2,3} Some of these patients form a subgroup of Felty's syndrome.^{2,4} The CD3(T3)+, HNK-1+ phenotype of the leukemic LGL associated with low natural killer (NK) activity in vitro suggests that these cells may have arisen from normal splenic LGL.^{5,6} In other diseases studies of neoplastic cells "frozen" at stages of maturation have provided important clues concerning the differentiation of their normal counterparts.⁷⁻¹⁰ Therefore, LGL leukemia may provide a model for the analysis of LGL differentiation. In this study, we utilized two-color immunofluorescent flow cytometry analyses together with a variety of in vitro induction systems to examine maturation of leukemic LGL. Our results show that CD3+ leukemic LGL can be directly induced to acquire NK function using either anti-CD3 monoclonal antibody (MAb) or interleukin 2 (IL 2).

METHODS

Patients. Patients were referred for evaluation of chronic lymphocytosis or neutropenia; three patients had polyarthritis, five had recurrent infections. Clinical details of patients 1, 6, 9, and 10 have been previously described.^{2,4} Examination of Wright-Giemsa stained blood smears showed that all patients had markedly increased numbers of LGL (LGL counts ranged from 1,700 to 20,000 cells/ mm^3 ; normal values in our laboratory: 223 ± 99 cells/ mm^3 , $n = 10$). Chronic neutropenia (<1800 neutrophils/ mm^3) was present in all patients with the exception of patient 5 who had a normal neutrophil count. Patient 2 had acquired cyclic neutropenia. All patients were studied on protocols approved by the Human Subjects Review Committee of Fred Hutchinson Cancer Research Center or the University of Washington.

Lymphocyte phenotyping. Peripheral blood or splenic mononuclear cells were isolated by Ficoll-Hypaque (Pharmacia, Piscataway, NJ) density gradient centrifugation and studied for expression of cell surface antigens using an EPICS 5 flow cytometer (Coulter Corporation, Hialeah, Fla) with direct one-color and two-color analysis using a panel of fluorescein-conjugated or R-phycoerythrin (PE)-conjugated mouse MAb, as previously described.¹¹ Normal human splenic tissue was obtained at time of harvesting of cadaveric kidneys for renal transplantation. The antigens recognized by the MAb are described using the current World Health Organization approved international nomenclature.¹² The following MAb have been verified by international workshop analyses: Dr Jeff Ledbetter (Oncogen Corporation, Seattle) kindly provided the G19-4 anti-CD3(T3), G17-2 anti-CD4(T4), and G10-1 anti-CD8 (T8) antibodies; Dr John Hansen (Fred Hutchinson Cancer Research Center, Seattle) kindly provided the 9.6 anti-CD2 (E-rosette receptor) and the 60.3 antibody to the Lp95-150 (LFA-1 associated) complex.¹³ Dr Toru Abo (University of Alabama, Birmingham, Ala) provided HNK-1.¹⁴ The HB10a MAb reacts with a major histocompatibility complex monomorphic determinant on Class II beta chains¹⁵ while the FC-1 MAb recognizes IgG Fc receptors (FcR; CD16) found on NK cells.¹¹ Competitive binding experiments show that FC1 recognizes an FcR epitope also recognized by Leu-11. The 3AC5 MAb recognizes a 220,000 dalton polypeptide (Lp220) of the T200 complex expressed on a subset of T helper cells.¹⁶ A high affinity (K_a approximately 10^{13} to 10^{15} mmol^{-1}) MAb 2A3 recognizing high-density IL 2 receptor (CD25) was purchased from Becton Dickinson (Mountain View, Calif) as a fluorescein conjugate.¹⁷

Cytotoxicity assay. Peripheral blood mononuclear cells were assessed for NK activity against the CD3- erythroleukemia cell line K562 using a four-hour ^{51}Cr -release assay, as previously described.¹⁸ For the sake of clear discussion, we operationally define "NK

activity" in this paper as MHC-nonrestricted cytotoxic activity against K562. Lytic units (LU) were calculated as LU per 10^6 cells for 30% specific lysis of 10^4 target cells.

Effectors. Mononuclear cells from normals and LGL leukemic patients were isolated by Ficoll-Hypaque density centrifugation. In some experiments, mononuclear cells were enriched for LGL by a modification of the technique of Timonen and Saksela.¹⁹ In brief, nylon wool nonadherent mononuclear cells were layered over Percoll step gradients (65%/60%/55%/50%/45%/40% steps) and centrifuged for five minutes at 3,000 g at room temperature. Two-color immunofluorescent flow cytometry analyses of cells from the 50%/55% fraction showed 85% to 95% enrichment in leukemic LGL with a CD3+, HNK-1+ or CD3+, FcR+ phenotype. However, approximately 5% to 15% of cells in this fraction were CD3+, HNK-1- or CD3+, FcR-. Consequently, in some experiments two-color immunofluorescent flow cytometry was utilized to sort for CD3+, HNK-1+ or CD3+, FcR+ leukemic cells.

Induction systems. Effector cells at a concentration of 1×10^6 /mL were incubated at 37 °C in a 95% air/5% CO₂ humidified atmosphere with anti-CD3 MAb, alpha-interferon (IFN; Interferon Sciences, New Brunswick, NJ), or purified IL 2 that had been made lectin-free by chromatographic purification (Lymphocult T-LF, Biotest, Frankfurt, West Germany) for various time periods. Kinetic experiments showed that maximal induction occurred after 48 hours; therefore, subsequent experiments utilized this incubation period. Based on dose-response experiments, a dose of 1 µg/mL of anti-CD3 MAb was used in subsequent experiments. Alpha-IFN was used at a concentration of 1,000 units per 10^6 cells, whereas IL 2 was used at an optimum concentration of 1%, except in one experiment in patient 2, in which an optimum concentration of 5% was used. Other control MAb tested at a concentration of 1 µg/mL included HB10a, 3AC5 anti-Lp220, and 60.3 anti-Lp 95-150. After the incubation period, cells were washed twice, counted, and placed into the NK assay at an appropriate concentration. In addition two-color immunofluorescent flow cytometry analyses were performed after the induction period.

RESULTS

Cell surface phenotype of LGL leukemic cells. One-color analysis showed that LGL leukemic cells from all patients expressed CD2, CD3, CD5, and HNK-1 (Table 1, top). However, when other markers were examined, hetero-

geneity and unusual surface phenotypes were evident in the leukemic cells: 4 of the 10 patients (1, 3, 8, and 9) had an abnormally high percentage of cells expressing FcR (CD16), while 6 of 10 patients (3, 4, 7, 8, 9, and 10) had increased expression of HLA-DR on leukemic cells. When the leukemic cells were examined by two-color analysis (Table 1, bottom), heterogeneity in surface phenotype was even more evident. For example, many leukemic cells from patients 1, 3, and 8 expressed both CD3 and FcR, a phenotype not generally seen in normal blood lymphocytes (see below). By inference, it was evident that some CD3+, FcR+ leukemic cells from patient 3 also expressed the HLA-DR and HNK-1 markers. Leukemic LGL from patient 5 also had an unusual phenotype, coexpressing CD4 and HNK-1.

A comparison of two-color analyses of normal lymphoid tissues to leukemic cells is shown in Fig 1. Normal peripheral blood mononuclear cells had few CD3+, HNK-1+ cells and no detectable CD3+, FcR+ cells. Normal splenic cells, in contrast, had large numbers of CD3+, HNK-1+ cells; in addition, surface antigen levels of HNK-1 were higher on splenic lymphocytes than on peripheral blood mononuclear cells. The phenotype of LGL leukemic cells resembled that of normal spleen, with large numbers of CD3+, HNK-1+ cells expressing high levels of surface HNK-1. Some leukemias were CD3+, FcR+ (as illustrated by patient 1), a phenotype not readily detectable in normal peripheral blood or splenic mononuclear cells. It should be noted that leukemic cell populations contained some CD3+, HNK-1- or FcR- cells, a point discussed in more detail below.

NK activity of LGL leukemic cells. The expression of FcR and HLA-DR antigens has been associated with NK activity in normal cells,²⁰⁻²² so it was of interest that leukemic LGL from some patients expressed these markers. Previously, we found low NK activity in patients 1, 6, 9, and 10.²⁴ Table 2 shows that NK activity was also low in other patients, including patients whose cells expressed the FcR and HLA-DR markers. NK activity in patient 7 was also less than normal (data not shown); NK activity in patient 10 was not tested.

Fig 1. Two-color immunofluorescence flow cytometry analyses of mononuclear cells from normal peripheral blood and spleen, and from LGL leukemic patients utilizing (A) PE-conjugated anti-CD3 MAb (red) versus fluorescein-conjugated HNK-1 MAb (green) and (B) PE-conjugated anti-CD3 MAb (red) versus fluorescein-conjugated anti-FcR MAb (green). 64×64 grid plots represent cell numbers on vertical axis versus log of red fluorescence (Y axis) versus log of green fluorescence (X axis), with every 4 to 5 dots representing approximately a doubling of fluorescence.

However, we found that LGL leukemic cells could be induced to express NK activity by incubation with anti-CD3 MAb (Table 2). As shown in Fig 2, as little as 50 ng/mL of anti-CD3 MAb produced a dramatic increase in NK activity (uninduced: LU = 0.001; induced: LU = 1.36). The kinetics of augmentation in NK activity are shown in Fig 3. Marked increase in NK activity was observed within 24 hours; maximum induction occurred by 48 hours and subsequently waned. Addition of anti-CD3 MAb at time 0 of a four-hour assay had no effect on NK activity, also indicating that an induction period was necessary to detect optimal activity. Increased NK activity was not accompanied by any obvious increased cell proliferation as cell numbers remained con-

stant throughout these experiments. A concentration of 1 μ g/mL of anti-CD3 MAb and an incubation period of 48 hours were thus selected as optimum conditions for induction. Table 2 shows results of representative experiments utilizing this induction system on peripheral blood mononuclear cells from five LGL leukemia patients. In each experiment there was marked augmentation (9- to >10,000-fold) in NK activity. Of note, this induction was also observed in leukemic cells from patients 2, 4, and 5 which did not express FcR. Similar results were obtained when MOLT-4 cell line was used as target cells (data not shown). Similar experiments showed that anti-CD3 MAb could also increase NK activity in normal peripheral blood mononuclear cells, though this effect was generally much less dramatic (1.3- to 15-fold).

We then examined the effect of other agents on NK induction. As shown in Table 2, NK activity in normal peripheral blood mononuclear cells was also augmented by both IFN and IL 2, as previously reported.²³⁻²⁶ IL 2 increased NK activity in some LGL leukemic cells, whereas IFN had no effect. Three other monoclonal antibodies were also examined for their effect on induction (data not shown). MAb recognizing the Lp 95-150 molecular complex (60.3) decreased NK activity in the LGL leukemic cells, as has been described in normal individuals.¹³ MAb to Lp220 (3AC5) and HLA-DR (HB10a) had little or no effect on NK activity in leukemic LGL.

Since NK activity in peripheral blood mononuclear cells from LGL leukemia patients could be induced by treatment with either anti-CD3 MAb or IL 2, we examined whether leukemic LGL could be directly activated or whether induction depended on the few remaining normal T cells. Similar to previous results, anti-CD3 MAb induced NK activity in highly purified (85% to 95%) nonadherent low-density CD3+, HNK-1+ leukemic LGL from patient 1 (in two separate experiments, uninduced: LU = 0.01 and 0.01, respectively; induced: LU = 0.33 and 0.91, respectively). Because there was still a small population (5% to 15%) of CD3+ cells with a normal T cell phenotype (ie, HNK-1-, FcR-) remaining in the enriched LGL leukemic populations, it was possible that normal T cells and not the LGL leukemia cells were being induced by anti-CD3 MAb or IL 2. To exclude that possibility, two-color immunofluorescent flow cytometry was utilized to positively sort out CD3+,

Table 2. Induction of NK Activity in Peripheral Blood Mononuclear Cells From LGL Leukemia Patients

Treatment	NK Activity (LU)*							
	Patients					Normal

*LU/ 10^6 cells for 30% specific lysis of 10^4 target cells. NK activity was assessed after 48 hours incubation with media or various agents, except in patient 2 where incubation period was 60 hours. NK activity of freshly isolated mononuclear cells from patients 1 to 5 was also assessed at time 0; results were similar to those obtained after 48 hours incubation with media alone. Anti-CD3 MAb was used at 1 μ g/mL; IFN at 1,000 U/ 10^6 cells, and IL 2 at a final concentration of 1% for all patients, except in patient 2 where IL 2 was used at concentration of 5%.

†Nylon-wool nonadherent cells.

‡ND, not done.

Fig 2. Dose-response characteristics of induction of NK activity in leukemic LGL by treatment with anti-CD3 MAb. Leukemic LGL were incubated with medium alone or with varying concentrations of anti-CD3 MAb for 48 hours at 37 °C in 5% CO₂ 95% air-humidified atmosphere. After incubation, cells were washed twice, counted, and used as effectors in NK assay.

FcR+ or CD3+, HNK-1+ leukemic LGL from CD3+, FcR- or HNK-1- T cells from patients 3 and 5. While CD3+, FcR+ leukemic LGL from patient 3 and CD3+, HNK-1+ (FcR-) leukemic LGL from patient 5 were directly activated by anti-CD3 MAb, no induction was seen in CD3+ T cells not expressing FcR or HNK-1 from these patients (Table 3). In patient 3, CD3+, FcR+ leukemic LGL were also directly activated by IL 2; again there was no effect of IL 2 on normal FcR- T cells from this patient.

We then examined whether induction in NK activity was associated with a change in surface antigen phenotype of the leukemic LGL. Using directly FITC-conjugated MAb and flow cytometric analysis, we found that induction with anti-CD3 MAb in leukemic LGL from patient 1 with a CD3+, HNK-1+, FcR+ phenotype did not change the density or frequency of expression of either CD3, HNK-1, FcR, or HLA-DR (data not shown). Similarly, there was no change in surface antigen expression on induced leukemic LGL from patient 5 (CD3+, HNK-1+, FcR-); in particular, there was no induction of FcR on these cells (data not shown). Augmentation of NK activity by anti-CD3 MAb or IL 2 was also not associated with expression of high-density IL 2 receptors on HNK-1+ leukemic cells (Fig 4).

DISCUSSION

The results of this study demonstrate several new findings in LGL leukemia. (1) NK activity (defined as MHC-nonrestricted cytotoxicity against K562 target cells) can be induced in leukemic LGL following incubation with either

anti-CD3 MAb or IL 2; (2) Activation with either anti-CD3 MAb or IL 2 resulted from a direct effect on CD3+ leukemic LGL and did not require CD3+ cells with a normal T cell phenotype (ie, CD3+, HNK-1-, FcR-); (3) Leukemic LGL and normal lymphocytes differed in their response to alpha IFN; and (4) Despite activation with anti-CD3 MAb or IL 2, leukemic LGL did not express detectable IL 2 receptors.

Since in other lymphoid malignancies, studies on neoplastic cells arrested at certain stages of differentiation have provided insight into the function of their normal counterparts,⁷⁻¹⁰ we examined the phenotype and function of leukemic LGL. Two-color immunofluorescent flow cytometry analyses revealed heterogeneity of phenotypes expressed on leukemic LGL. However, in all patients the majority of leukemic LGL coexpressed CD3 and HNK-1 and had little NK function in vitro. Confirming previous findings,^{5,6} we found that cells with this phenotype were present in normal spleen. Most patients with LGL leukemia have splenomegaly, and previous immunopathologic studies have shown involvement of splenic red pulp cords with leukemic CD3+, HNK-1+ cells.^{2,4} Taken together, these findings suggest a splenic origin of this disease.

Previous studies had referred to this disease as T gamma lymphoproliferative disorder, since LGL from these patients expressed CD2 and FcR.¹ Of note, cells from only four of our patients expressed FcR, thought to be a specific NK marker.^{21,22} This CD3+, HNK-1+, FcR+ phenotype of some leukemic LGL has not been readily detectable in normal fetal or adult lymphoid tissue,⁶ although peripheral blood mononuclear cells from 3 of 46 presumably normal individuals were found to have >5% circulating CD3+, FcR+ LGL.²⁷ Because of this phenotypic heterogeneity, it would seem preferable to us to refer to this disease as LGL leukemia rather than T gamma lymphoproliferative disorder.

Leukemic LGL from these patients had little NK activity in vitro, consistent with data showing that normal lymphocytes coexpressing HNK-1 and CD3 (ie, FcR-) have little cytotoxicity.¹⁹ However, functional maturation in CD3+ leukemic LGL could be consistently achieved by treatment with anti-CD3 MAb. Anti-CD3 MAb has been reported to induce cytotoxic T lymphocyte activity in normal peripheral blood mononuclear cells.^{28,29} Furthermore, induction of cytotoxic activity by anti-CD3 MAb in normal LGL has been

Fig 3. Kinetics of anti-CD3 MAb-induced augmentation of NK activity in leukemic LGL. Anti-CD3 was used at a concentration of 1 µg/mL; leukemic LGL were cultured at a concentration of 1×10^6 /mL. Total numbers in culture after 24 hours incubation were: 11.4×10^6 , media control, and 11.5×10^6 , anti-CD3; after 48 hours: 10.1×10^6 , media control, and 11.5×10^6 , anti-CD3; after 72 hours: 11.0×10^6 , media control, and 10.4×10^6 for anti-CD3; and after 96 hours: 9.6×10^6 , media control, and 9.2×10^6 , anti-CD3 cultures.

Table 3. Induction of NK Activity of CD3+ Leukemic LGL Purified by Cell Sorting

Cell Population	NK Activity (LU)*				
	Patient 3			Patient 5	
	Media	Anti-CD3	IL 2	Media	Anti-CD3
Unsorted	100	151	714	<0.001	0.77
CD3+ Leukemic†	143	250	294	<0.001	41.7
CD3+ Normal‡	<0.001	<0.001	<0.001	<0.001	0.008

*LU/10⁶ cells for 30% specific lysis at 10⁴ targets. NK activity was assessed after 48 hours incubation with media or various agents. Anti-CD3 MAb was used at 1 µg/mL, and IL 2 at a final concentration of 1%.

†CD3+ "leukemic" cells were obtained by two-color sorting, and defined as either CD3+, FcR+ (patient 3), or CD3+, HNK-1+ cells (patient 5). Purity of these cell populations was >97% in both cases.

‡CD3+ "normal" cells were CD3+, FcR- cells (patient 3) or CD3+, HNK-1- cells (patient 5) obtained by cell sorting.

noted, although this effect depended on normal T cells,³⁰ in contrast to our findings with leukemic LGL. The dose-response characteristics of this induction system were similar to that seen in normal LGL, with augmentation occurring with as little as 10 ng/mL of anti-CD3 and with a plateau effect seen at higher concentrations of MAb. Recently Lanier et al have induced cytotoxicity by treatment with anti-CD3 MAb in CD3+, FcR+ cells from short-term IL 2-dependent cultures derived from normal individuals.²⁷ Our findings, in addition, demonstrate that CD3+, HNK-1+ leukemic LGL that are either FcR+ or FcR- can be

directly activated by treatment with anti-CD3 MAb. However, normal T cells from these patients (CD3+, HNK-1- or CD3+, FcR-) could not be similarly activated. Taken together, these findings suggest that anti-CD3 MAb induces cytotoxicity through a direct effect on CD3+, HNK-1+ LGL.

Treatment with IL 2 also induced NK activity in leukemic LGL from 2 of 4 patients. Augmentation of NK activity by IL 2 in normal individuals has been noted previously,^{25,26} though the mechanism has not been clearly ascertained. This effect is not dependent on cell proliferation³¹ or on expression of IL 2 receptors that are recognized by the anti-TAC MAb on LGL.^{31,32} Production of gamma IFN after induction with IL 2 has been demonstrated by some investigators³¹; others have not found a contributory role for either alpha or gamma IFN in this induction.³² CD3-, IL 2 receptor- LGL were shown to respond directly to recombinant IL 2³¹; further work has shown that IL 2-responsive LGL in normal individuals are CD3-, FcR+ (HNK-1+ or -). Of note, no augmentation of NK activity was seen in peripheral blood mononuclear cells coexpressing CD3 and HNK-1³² or in CD3+, FcR+ LGL derived from IL 2-dependent short-term cultures.²⁷

The mechanism of induction of NK activity in leukemic LGL treated with IL 2 remains to be determined. Similar to findings in normal LGL, we did not find evidence for proliferation (as measured by cell counts) or expression of high-density IL 2 receptors. It is possible that alternative IL 2 receptors not recognized by the anti-IL 2 receptor may be involved in this immunoregulatory effect of IL 2.³¹ Alpha IFN does not appear to be involved in this induction system since it did not augment NK activity in leukemic LGL, unlike its effect on normal cells. In contrast to normal peripheral blood LGL,³² CD3+, HNK-1+ leukemic LGL lacking FcR could be directly activated by IL 2. Furthermore, induction of NK activity by IL 2 was also observed in CD3+, FcR+ leukemic LGL.

The activation of normal T cells and CD3+ leukemic LGL differs in that functional maturation of CD3+ leukemic LGL induced by treatment with either anti-CD3 MAb or IL 2 was not accompanied by either cell proliferation or IL 2 receptor induction, even though the anti-CD3 MAb used in this study is a potent activator of normal T cell proliferation.³³ Recently it has been shown that certain putative growth factors may instead act as differentiation factors depending on the stage of differentiation of the

Fig 4. Lack of expression of IL 2 receptor on leukemic LGL from patient 1 even after activation with anti-CD3 MAb. One- (A and B) and two-color (C and D) flow cytometry analyses of uninduced (A and C) and induced (B and D) leukemic LGL utilized PE-conjugated anti-IL 2 receptor MAb (red) and fluorescein-conjugated HNK-1 MAb (green). 64 by 64 grid plots represent cell numbers on vertical axis versus log of red fluorescence (Y axis) versus log of green fluorescence (X axis) with every 4 to 5 dots representing approximately a doubling of fluorescence. LU/10⁶ effector cells for 30% killing of 10⁴ target cells.

induced cell.^{34,35} Our results suggest that whether or not CD3+ cells are induced to proliferate or differentiate by anti-CD3 MA b or IL 2 may depend on their state of differentiation and/or surface phenotype.

The results of these studies indicate that LGL leukemia may serve as a useful model for evaluation of LGL maturation and activation. Furthermore, these induction systems may offer an in vitro method for assessing potential therapy in these patients. The prominent autoimmune manifestations of LGL leukemia suggest an underlying defect in B-cell

immunoregulation. Since normal LGL can regulate B cells,^{36,37} the clonal expansion of functionally immature LGL may result in unopposed B cell activity. Indeed, LGL from some of these patients demonstrate impaired suppression of immunoglobulin biosynthesis, in vitro.^{2,38} Augmentation of LGL function by immunomodulatory agents therefore, may be clinically beneficial. Further studies in additional patients with LGL leukemia are needed both to assess fully the in vitro effectiveness of such agents as well as to explain their mechanism of action.

Immunoglobulin and T Cell Receptor Gene Rearrangements in Human Lymphoma and Leukemia

By Michael E. Williams, Donald J. Innes, Jr, Michael J. Borowitz, Mark A. Lovell, Steven H. Swerdlow, Paul E. Hurtubise, Russell K. Brynes, Wing C. Chan, Gerald E. Byrne, Jr, Clarence C. Whitcomb, and Christopher Y. Thomas, IV

DNA samples from blood leukocytes or tumor biopsies of 45 patients with phenotypic B or T cell neoplasms were analyzed for rearrangements of the immunoglobulin (Ig) or T cell receptor (TCR) genes by Southern blot hybridization analysis. Rearrangements of the Ig heavy chain joining region genes (J_H) were present in DNA from each of 28 B cell lymphomas and leukemias; 14 of 21 of these tumors also had rearrangements of the Ig kappa light chain joining (J_K) or deleting element (K_{del}) genes. Conversely, 16 of 17 T cell lymphomas and leukemias had rearranged TCR beta chain genes. One B cell and one T cell tumor had rearrangements of both Ig and TCR genes. There was a strong correlation between the rearrangements of specific genes

and the immunophenotype of the tumor: (1) J_H rearrangement without TCR beta chain rearrangement occurred only in B cell tumors; (2) TCR beta chain rearrangement with or without J_H rearrangement occurred only in T cell tumors, with one exception; and (3) J_K and K_{del} rearrangements were found only in B cell tumors. Thus, rearrangements of the Ig heavy and light chain genes and the TCR beta chain genes were found to be highly sensitive markers of monoclonal human lymphomas and lymphoid leukemias, with the type of gene rearrangements well correlated with the cell lineage of these neoplasms.

© 1987 by Grune & Stratton, Inc.

NORMAL B and T lymphocytes can express a virtually unlimited repertoire of antibody and T cell receptor specificities. Such diversity is made possible by variations in the assembly of the immunoglobulin and T cell receptor genes.¹⁻¹² Discontinuous genes encoding the variable regions of immunoglobulin (Ig) heavy and light chains undergo somatic DNA rearrangement during the differentiation of lymphoid stem cells into B lymphocytes.^{1,2} Similarly, rearrangements of the T cell receptor (TCR) alpha and beta chain genes occur during the early stages of T lymphocyte differentiation.³⁻⁶ Because of the large number of possible gene rearrangements, the structure of Ig or TCR genes is virtually unique for each B or T lymphocyte.

Southern blot assays of DNA from human lymphoid neoplasms have shown that the tumor cells of individual neoplasms generally contain a single pattern of Ig or TCR gene rearrangement, with variations in the structure of these rearrangements from tumor to tumor.¹³⁻¹⁷ These findings confirmed the monoclonal origin of these tumors and showed that Southern blot assays can detect clonal proliferations of lymphocytes which comprise as little as 1% to 5% of the total cells in the tissue sample.¹⁴ The DNA from polyclonal proliferations of lymphocytes do not contain detectable specific gene rearrangements because the structure of the rearranged gene(s) varies from cell to cell.^{15,16}

One advantage of gene rearrangement assays is that the monoclonality of lymphoproliferative lesions can be established in the absence of the expression of cellular phenotypic markers, such as the monotypic expression of Ig kappa or lambda light chains. Assays for gene rearrangements have been used to establish the B cell origin of certain human lymphoid tumors. Thus, "non-T, non-B" acute lymphoblastic leukemia,^{13,18} hairy cell leukemia,¹⁹ lymphoid blast crises of chronic myelogenous leukemia,^{20,21} and certain lymphomas¹⁵ were shown to arise from B lymphocytes by virtue of rearranged Ig heavy and light chain genes. However, Ig heavy chain gene rearrangements are not totally specific for B cells, since they have been described in T cell leukemia,²² acute nonlymphocytic leukemia,²³ and in some murine T cell lymphomas and cultured T cell lines.^{24,25} TCR beta chain genes (T_{beta}) have been shown to rearrange in T cell lines and

in some human T cell tumors, but the specificity of such rearrangements has not yet been fully defined.^{10,11,17,26}

The purpose of the present study was to compare the frequency and pattern of Ig and T_{beta} gene rearrangements in a wide variety of histopathologically and immunophenotypically defined human lymphomas and leukemias.

MATERIALS AND METHODS

Patients. Forty-five patients with lymphoma or lymphoid leukemia were included in the study, selected on the basis of tumor morphology and/or immunophenotype. This investigation was approved by the Human Investigations Committee of the University of Virginia.

Tissue accrual and storage. Tissue samples were obtained from excess material from biopsies or blood samples obtained for diagnostic purposes. After submitting necessary tissue for histopathologic and immunocytochemical studies, the remaining tissue or blood cells were snap-frozen in liquid nitrogen or a dry-ice-methanol bath and stored at -70°C or in liquid nitrogen vapors.

Morphologic classification. Standard morphologic criteria for the diagnosis and subclassification of acute and chronic lymphocytic leukemias were used, based upon Wright's stain and cytochemical studies of blood or bone marrow cells with periodic acid-Schiff reagent (PAS), myeloperoxidase, nonspecific esterase (NSE), and Oil Red O.^{27,28}

Non-Hodgkin's lymphomas were classified by the New Working Formulation of the National Cancer Institute.²⁹ Plastic or paraffin-

embedded biopsy samples were stained with hematoxylin and eosin for interpretation.

Immunocytochemical phenotyping. The cellular phenotype of tumor samples was determined by immunoperoxidase staining of tissue sections or by analysis of cell suspensions by indirect immunofluorescence or immunoperoxidase staining or by flow cytometry.^{30,31} At least 25% of tumor cells were required to express an antigen in order for the tumor to be considered positive for that marker. Tumors were classified as B cell in origin if the tumor cells were positive for the presence of surface or cytoplasmic Ig and/or for the monoclonal antibodies Leu 12, Leu 14, B1, or B2. Tumors were classified as T cell in origin if the cells expressed no B cell markers and expressed one or more of the pan T cell markers Leu 1, Leu 4, Leu 5, and Leu 9. T cell subset markers including markers for T helper cells (Leu 3A, OKT4), T suppressor cells (Leu 2A, OKT8), thymic cells (Leu 6, OKT6), and natural killer cells (Leu 7, Leu 11) were assayed.

The nonspecific cellular markers HLA-Dr (Ia-like), common acute lymphocytic leukemia antigen (CALLA, J5), and terminal deoxynucleotidyl transferase enzyme (Tdt) were also assayed in some cases.

Immunoglobulin gene rearrangement. DNA was isolated from tissue samples by standard phenol-chloroform extraction and ethanol precipitation.³² Five micrograms of DNA from each sample were digested overnight with 5 to 10 U/mcg of the restriction enzyme Bam H1 or Eco R1 (Bethesda Research Laboratories, Inc, Gaithersburg, MD). The resulting DNA fragments were separated by electrophoresis on 0.6% agarose gels, and the DNA was transferred to a nylon membrane (Zeta Probe, BioRad Laboratories, Richmond, Calif) by the method of Southern.³³ Membrane-bound DNA was then hybridized with a nick translated probe³⁴ from the Ig heavy chain joining region (J_H). The J_H probe, a 6 Kb Bam H1-Hind III genomic fragment containing the J_H region, was cloned into the plasmid pBR 322 (kindly provided by Dr Philip Leder, Harvard University, Boston). The probe was gel purified from plasmid DNA prior to nick translation. Specific activity of the ^{32} P-labelled J_H probe was 1.5 to 3.0×10^8 cpm/mcg DNA. Hybridization was carried out at 65°C for 18 to 22 hours followed by high stringency washing of the blot. Membranes were exposed to Kodak XRP-5 film at -70°C for 1 to 10 days with intensifying screens. The blots were then stripped in 0.4 N NaOH , neutralized, and stored in prehybridization mix prior to rehybridizing with another probe.

Kappa light chain gene rearrangements were detected in Bam H1 genomic DNA digests using two probes. A 4.6 Kb Hind III fragment

containing the kappa joining region genes (J_K) was subcloned in pBR 322 from a genomic kappa constant and joining gene probe (provided by Dr Philip Leder). A 2.5 Kb Bam H1-Hind III fragment containing the kappa deleting element (K_{Del}) was cloned in pBR 322 (kindly provided by Dr Stanley Korsmeyer, National Institutes of Health³⁵).

Rearrangements of the Ig genes were detected by the appearance of non-germline DNA band(s) hybridizing to the ^{32} P-labelled J_H probe (Fig 1) and the appearance of new band(s) and/or deletion of the germline band with the J_K probe (Fig 1). The K_{Del} genes are located 3' of the kappa light chain constant region (C_K) locus on chromosome 2p, and are postulated to mediate deletion of C_K and J_K following unsuccessful rearrangement of a kappa allele.³⁵ Thus, a tumor with successful rearrangement of the first kappa allele should show germline K_{Del} genes. A tumor expressing kappa light chains from rearrangement of the second allele (the first being nonfunctionally rearranged) usually contains two germline K_{Del} genes, although K_{Del} rearrangement may be seen in the nonfunctional allele if C_K has been deleted. If both kappa alleles are deleted, as in some lambda producing tumor cells, both K_{Del} genes should be rearranged. Autoradiograph patterns of K_{Del} rearrangements are shown in Fig 2.

T cell receptor gene rearrangement. T_{beta} gene rearrangements were assayed as described above for the Ig genes, using Bam H1, Eco R1, and Hind III restriction enzyme digests of tumor DNA. The probe was a cDNA clone of the TCR beta chain, containing both variable and constant regions (kindly provided by Dr Tak Mak, University of Toronto). This 770 base pair probe was cloned into the Pst I site of pBR 322, and was gel purified from plasmid DNA prior to nick translation. In some cases hybridization was performed using a 440 base pair constant region probe obtained by Hinc II restriction enzyme cleavage of the intact cDNA, with purification of the constant region fragment by sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

Criteria for rearrangement of T_{beta} genes included the appearance of new bands on the autoradiographs of tumor DNA plus the partial or complete deletion of constant region germline bands (Fig 3).

RESULTS

A total of 45 patients were included in this study. In some cases serial biopsies or multiple simultaneously obtained tissue samples were available. In all cases the extracted DNA from the frozen specimens was well preserved, with little or no degradation.

Fig 1. Rearrangement patterns of immunoglobulin heavy chain joining region (J_H , lanes a–f) and kappa light chain joining region (J_K , lanes g–i) genes on Eco R1 and Bam H1 digests of tumor DNA. Germline bands (dash marks, lanes a, d, g), rearranged bands (r), and pseudogene bands (p) plus the germline band size in kilobase units are indicated. Lane a, control DNA. Lane b, partial deletion of germline J_H band, one rearranged allele (case no. 85-8, Table 2). Lane c, one rearranged and one deleted J_H allele (case no. 85-12, Table 1). Lane d, control DNA. Lane e, one rearranged J_H allele (case no. 83-8, Table 1). Lane f, both J_H alleles rearranged, residual germline band from nontumor cell DNA (case no. 84-16, Table 2). Lane g, control DNA. Lane h, one rearranged and one deleted J_K allele (case no. 83-12, Table 1). Lane i, deletion of both J_K alleles (case no. 83-2, Table 2). See restriction enzyme maps, reference 15.

Fig 2. Rearrangement patterns of immunoglobulin kappa light chain deleting element (K_{Del}). Lane a, control DNA; germline pattern with 14Kb germline band (dash mark) and approximately 3Kb pseudogene (p). Lane b, one rearranged K_{Del} allele (case no. 84-3, Table 2). Lane c, both K_{Del} alleles rearranged (case no. 83-12, Table 1). DNA was digested with Bam H1. See reference 35.

Lymphoid leukemia. Nine cases of acute lymphoblastic leukemia (ALL) were evaluated. The DNA was extracted from bone marrow cells in six cases, peripheral blood cells in two cases, and from a testicular biopsy in one case (case no. 85-20). The tumor cell phenotypes and results of the gene

rearrangement assays are presented in Table 1. Three cases of "pre-B cell" ALL showed rearrangement of Ig heavy chain alleles by J_H probe hybridization. Two showed germline T_{beta} genes; the remaining case could not be studied for the T_{beta} marker due to inadequate material.

Six T cell ALLs were evaluated; one was HLA-Dr positive and four were J5 positive. Cells from all six were found to have T_{beta} gene rearrangement; one (case no. 83-8) also had rearrangement of one Ig J_H allele by Eco R1 (Fig 1, Lane e) but not Bam H1 restriction enzyme digestion of the tumor DNA. J_K and K_{Del} gene rearrangements were not present in the five T cell ALLs tested, including the tumor with J_H rearrangement. Detection of J_H gene rearrangements on Eco R1 but not Bam H1 digests has been noted previously in ALL.¹³

Two cases of hairy cell leukemia had Ig gene rearrangement without TCR gene rearrangement (Table 1), consistent with the B cell lineage previously reported for this neoplasm.¹⁹

B cell lymphomas. Twenty-three phenotypic B cell lymphomas were studied (Table 2). Eighteen of 19 tumors studied for surface or cytoplasmic Ig were positive, as were all 14 tumors tested with B1, B2, Leu 12, and/or Leu 14 monoclonal antibodies. Two follicular mixed small cleaved and large cell lymphomas did not have phenotypic marker studies performed (case nos. 83-2 and 85-23), but were included in this category because virtually all true follicular lymphomas are B cell in origin.^{36,37}

Each of the 23 B cell lymphomas had rearrangement of one or both Ig J_H alleles (Table 2). Six of seven tumors had J_K rearrangements and/or deletions, while 12 of 17 had K_{Del} rearrangements. One diffuse large noncleaved cell lym-

Fig 3. Rearrangement patterns of T cell receptor beta chain genes (T_{beta}) on Bam H1 and Eco R1 digests of tumor DNA. The T_{beta} probe was from a cDNA clone containing both constant region (23Kb band Bam H1, 12 and 4.2Kb bands Eco R1) and variable region genes (2.0, 3.3, and 6.5Kb bands Bam H1; 2.4 and 5.4Kb bands Eco R1). Lanes a and d, control DNA; germline patterns (dash marks). Lane b, one rearranged (r), one deleted T_{beta} constant region allele (case no. 84-5, Table 1). Lane c, both constant region alleles rearranged (case no. 83-8, Table 1). Lane e, deletion of first constant region alleles (case no. 83-8). Lane f, deletion of first constant region alleles and both variable region bands (T cell line HPB-MLT). Lane g, deletion of first constant region alleles, three non-germline bands representing rearranged variable and/or constant region genes (T cell line HSB). Lane h, one rearranged band (T cell line JM). See restriction enzyme maps, references 43, 47.

phoma positive for surface IgM lambda (case no. 85-18) did not show the predicted pattern of having both kappa alleles rearranged.^{16,18} Instead one germline and one rearranged band were present with both J_K and K_{Del} probes. It is unlikely that these bands represent rearranged genes comigrating in the germline position because the germline fragments for J_K and K_{Del} are of different size (12 kb and 14 kb, respectively). This pattern of gene rearrangement is unexpected since B cells normally attempt to rearrange both kappa alleles before proceeding to lambda light chain rearrangement.^{16,18} However, a similar exception to this normal hierarchical Ig gene rearrangement was recently reported for a lambda-producing human lymphoid cell line.³⁸

One B cell lymphoma had detectable T_{beta} gene rearrangement on both Bam H1 and Eco R1 digests of tumor DNA, in addition to rearrangements of J_H and K_{Del} (case no. 84-11). This small noncleaved cell (Burkitt's) lymphoma stained positive with Oil-Red-O but negative with myeloperoxidase, NSE, and PAS. The tumor cells expressed cell surface IgM_K, HLA-Dr, and Leu 12, but they failed to react with antibodies to J5, Leu 1, Leu 4, and Leu 9 and did not form E rosettes.

T cell lymphomas. Eleven T cell lymphomas were evaluated (Table 3). A variety of histologic types were represented, and all were negative for surface or cytoplasmic Ig and B cell monoclonal antibody markers. Most tumors were positive for the pan-T cell markers detected by the Leu 5, Leu 9, or Leu 4 antibodies. Six tumors expressed Leu 3A (T helper cells), one expressed Leu 2A (T-suppressor cells), one expressed both Leu 3A and Leu 2A, and three were negative for both markers.

Ten of the eleven tumors had rearranged T_{beta} genes. The one tumor in germline configuration was a lymphoblastic lymphoma which was Leu 1, 5, and 9 positive, but negative for the Leu 4 monoclonal antibody and the Leu 2A and 3A subset markers (case no. 84-6). The lack of expression of mature T cell markers, including the TCR complex detected by the Leu 4 antibody, suggested that this neoplasm has arisen from a primitive T cell. The absence of detectable T_{beta} gene rearrangements may have been due to the immaturity of the tumor cells.

No Ig gene rearrangements were seen in these phenotypic T cell lymphomas.

Analysis of DNA from normal tissues and other lymphoproliferative states. DNA was extracted from peripheral blood cells or cultured skin fibroblasts from 27 normal human donors. Germline T_{beta} genes were present in all cases using Bam H1, Eco R1, and Hind III restriction enzyme DNA digests. No K_{Del} polymorphisms were seen in 15 normal DNA samples digested with Bam H1, Eco R1, or Hind III.

Tissues from several other lymphoproliferative diseases were also available for study (data not shown). The DNAs from a dermatopathic lymph node, from lymph nodes of three patients with acquired immune deficiency syndrome (AIDS)-associated lymphadenopathy, and biopsies from two cases of thymic hyperplasia lacked Ig or T_{beta} gene rearrangements. Interestingly, analysis of DNAs from both the thymus samples showed a decreased intensity in the bands representing the unrearranged TCR beta chain constant region genes. This was most evident in the partial deletion of the 12Kb Eco R1 germline band, which indicated that a substantial proportion of the thymocytes contained rearrangements of the first constant region locus of the T_{beta} genes.¹⁷ The absence of any detectable rearranged band in the autoradiographs revealed the polyclonal nature of this process. No rearrangements were present in six cases of Hodgkin's lymphoma (four nodular sclerosis, one mixed cellularity, and one lymphocyte predominant histology).

DISCUSSION

Rearrangements of the Ig and TCR genes were found to be highly sensitive markers for a wide spectrum of histopathologic and immunologic phenotypes of B and T cell neoplasms. Southern blot assays for somatic rearrangements of the J_H region of the Ig heavy chain gene, the J_K and K_{Del} regions of the Ig kappa light chain genes, and the TCR beta chain gene were positive in 44 of the 45 lymphoid leukemias and lymphomas that were studied. These observations are in agreement with the concept that Ig or TCR gene rearrangements occur early in the differentiation of B or T lymphocytes and that the vast majority of human lymphoid neoplasms are monoclonal in origin.^{13,18,39,40}

There was a strong correlation between the rearrangements of specific gene regions in the cellular DNA and the

immunophenotype of individual tumors. First, J_H rearrangement without T_{β} rearrangement occurred only in B cell tumors. Second, T_{β} rearrangements with or without J_H rearrangement occurred only in T cell tumors with one exception. Third, J_K and K_{Del} rearrangements were highly specific for B cell tumors. Thus, based on J_H and T_{β} gene rearrangements, one could correctly predict whether a given lymphoid tumor was of B or T cell phenotype in 42/45 cases (93%). In this series assays for rearrangement of the J_K and K_{Del} genes established the tumor phenotype in one case with coexisting J_H and T_{β} rearrangements, but otherwise did not improve the ability to predict tumor phenotype.

The DNA from three tumors showed atypical patterns of Ig and TCR gene rearrangements. One lymphoblastic lymphoma of T cell phenotype had no detectable gene rearrangements (case no 84-6, Table 3). This may represent a false-negative assay in which the DNA fragments from the rearranged allele comigrated with those genes in the germline configuration, although this was unlikely to have occurred in all restriction enzyme digests. Alternatively, the failure of these cells to express the Leu 4 molecule, an integral part of the T cell receptor,⁴¹ may have reflected the absence of T_{β} gene rearrangements and production of a functional TCR beta chain. The phenotype of the lymphoma cells was similar to that of a subset of normal immature thymocytes that may not contain rearranged TCR genes.^{39,40} One T cell ALL contained rearrangement of the T_{β} genes and of the Ig J_H region (case no. 83-8, Table 1). Rearrangement of Ig mu-chain genes has been described in T cell ALL.²² J_H rearrangement in T cell ALL may be analogous to rearrangements in some murine T cell lymphomas in which a fusion of Ig heavy chain diversity genes (D_H) and J_H segments has occurred.^{24,25} In Southern blot assays these fusions appear as rearrangements of the Ig J_H genes. However, the variable region sequences are absent and these rearranged genes are incapable of encoding functional Ig heavy chain molecules.

The third atypical tumor contained rearrangements in each of the three gene regions that were analyzed. This small noncleaved cell (Burkitt's) lymphoma (no. 84-11, Table 2) expressed cell surface IgM κ , with no evidence of a coexisting T cell clone to account for the T_{β} rearrangement. Others have also found so-called bigenotypic rearrangements in up to 11% of phenotypic B and T cell tumors.^{42,43} O'Connor et al²⁶ reported that Ig heavy chain and T_{β} rearrangements coexisted in three of 52 cases of B cell chronic lymphocytic leukemia and lymphoma. Pelicci et al⁴² found such dual rearrangements in five of 33 B cell and in two of 30 T cell malignancies. The frequency of such nonlineage specific rearrangements will be an important consideration when attempting to use Ig and TCR gene rearrangement assays to assign the cell lineage of phenotypically undefined lymphoid neoplasms.

This and other recent reports have underscored the usefulness of assays for T_{β} gene rearrangements as the first reliable method for establishing monoclonality in T cell proliferations.^{17,26,43-47} Although T cell lymphomas may display abnormalities in the expression of certain T cell differ-

entiation antigens, this finding is not invariable and only indirectly infers monoclonality.⁴⁸ T_{β} gene rearrangements were highly sensitive markers of T cell neoplasms and were present in 16 of our 17 T cell cases and in nearly all T cell leukemias and lymphomas reported by others.^{17,26,42-47} Important in this regard is the apparent low frequency of polymorphisms for the T_{β} genes, occurring in none of our 27 normal human DNA samples. However, rare polymorphisms at the Eco R1 or Hind III sites have been noted by others.^{17,43}

Deletion of the first TCR beta chain constant region (12kb band on Eco R1 digests; Fig 3) without new rearranged bands was present in five of six T cell ALLs in this series, a pattern also noted in 11 of 15 T cell leukemias reported by Rabbitts et al.⁴⁴ Unlike polyclonal proliferations, rearranged bands are present on Bam H1 and Hind III DNA digests indicating both the monoclonal nature of ALL and the frequent use of the second TCR beta chain constant gene locus.⁴⁴ Whether this rearrangement pattern is a nonrandom event in some T cell ALLs is uncertain. It was not seen in any of our T cell lymphomas, all of which had rearranged bands on Eco R1 digests (except case no. 84-6).

Assays for rearrangements of K_{Del} proved to be very reliable in identifying Ig light chain gene rearrangements. The kappa constant or joining regions are often partially or completely deleted, especially in lambda-producing B cells.³⁵ The deletion of these sequences may not be apparent when studying DNA in which the tumor cells comprise only a small proportion of the total tumor sample, as nontumor cells will contribute to the germline bands on autoradiographs creating a false-negative assay. Specific assays for rearrangement of lambda light chain genes require the use of additional restriction enzyme digestions, and the interpretation of these assays is often difficult due to the high frequency of structural polymorphisms in this locus.^{49,50} We found no Bam H1, Eco R1, or Hind III restriction enzyme structural polymorphisms in the DNA near K_{Del} in the 15 normal samples that were tested. Since one K_{Del} allele is rearranged for each nonfunctional and deleted C_K gene, it should be possible to predict the presence of nonfunctional or potentially functional kappa genes.³⁵ The correlation of Ig light chain expression with the pattern of gene rearrangements in our B cell tumors generally supports this concept (Table 2). Since the K_{Del} and J_K (or C_K) germline bands are on separate Bam H1 fragments (14 Kb and 12 Kb, respectively) one could theoretically perform a single step Southern blot hybridization using a mixture of labelled K_{Del} and J_K (or C_K) probes to assess the presence of light chain gene rearrangements.

Several other observations made during this study deserve comment. First, the reliable detection of Ig and TCR gene rearrangements by Southern blot assay required analysis of separate samples of tumor DNAs that were digested with different restriction endonucleases, an observation that has been made by others.¹³ Second, none of the tumors contained Ig light chain gene rearrangement in the absence of heavy chain gene rearrangements, although such cases have been reported by others.⁵¹ Finally, the DNAs from all four T cell ALLs that expressed CALLA had evidence of TCR beta

chain gene rearrangements, though only one demonstrated a rearrangement in the Ig heavy chain genes. This observation is identical to that of Ginsburg et al,⁵² and verifies that expression of CALLa is not limited to B lymphocytes or B cell malignancies.

This work shows Ig and TCR gene rearrangements to be highly sensitive though not entirely specific in identifying lymphoid neoplasms of T or B cell origin. These assays have the potential to establish the cell lineage of phenotypically undifferentiated lymphomas and leukemias, and to detect monoclonal B or T cell populations in immunopathologically nondiagnostic lymphoproliferative lesions. However, the role of gene rearrangement assays in the clinical management of patients can only be determined by prospective clinicopathologic studies.

NOTE ADDED IN PROOF

Since submission of this manuscript, case no. 85-18 (Table 2) has been studied with the C_K probe. This showed that both C_K alleles were deleted as expected for a lambda-producing B cell tumor. However, one of the alleles may have been deleted by an aberrant mechanism since one K_{Del} element retained the germline configuration.

ACKNOWLEDGMENT

We thank Drs Stanley Korsmeyer, Philip Leder, and Tak Mak for kindly providing the immunoglobulin and T cell receptor probes used in this study. We thank Linda Wilson for assistance in performing some of the Southern blot experiments, and Dr Wendy Maury for providing normal human fibroblast DNA. We also thank Linda Wilson-Saunders for preparation of the manuscript.

Evidence Favoring Lineage Fidelity in Acute Nonlymphocytic Leukemia: Absence of Immunoglobulin Gene Rearrangements in FAB Types M4 and M5

By S.P. Ackland, C.A. Westbrook, M.O. Diaz, M.M. Le Beau, and J.D. Rowley

The concept of lineage fidelity in acute leukemia has recently been challenged by the finding of rearrangements of the immunoglobulin heavy chain genes in a leukemic cell line and in a small number of sporadic cases of acute nonlymphocytic leukemia with a monocytic phenotype. We therefore screened leukemic blood or bone marrow samples of 33 adult patients with acute nonlymphocytic leukemia of FAB types M4 (23 patients) and M5 (10 patients); 28 were obtained at diagnosis and 5 at relapse. All cases were well characterized pathologically and histochemically. Cytogenetic analysis performed in each case demonstrated karyotypes that were representative of those generally

seen in these types of leukemia, with a clonal abnormality present in all except 9 of 32 patients who were successfully studied. DNA prepared from each sample was digested with the restriction enzyme BamH1 and analyzed by Southern blot hybridization to probes for the J_H region of the immunoglobulin heavy chain. All 33 cases had DNA retained in the germline configuration with no evidence of rearrangement. This finding supports the concept of lineage fidelity, and suggests that true interlineage infidelity, myeloid to lymphoid, is a rare occurrence in adult acute nonlymphocytic leukemia.

© 1987 by Grune & Stratton, Inc.

THE concept of lineage fidelity in acute leukemia states that the leukemic clone is derived from a single phenotypically defined cell, that markers with specificity for normal differentiation pathways maintain that specificity in the leukemic clone, and that differentiation is arrested rather than being deranged.¹⁻³ Furthermore, it implies that leukemic cells do not cross lineages. This concept remained largely unchallenged until recently when several investigators independently reported coexpression of lymphoid and myeloid markers in cells from some leukemic cell lines and from fresh leukemic tissue.⁴⁻⁶ This occurrence of "lineage infidelity" suggests that the leukemic cell may arise from a less well-differentiated stem cell precursor, which is capable of producing differentiated cells with features of both lineages.³ The investigation of leukemic lineage has led to many insights into the understanding of both normal and abnormal hematopoietic cell differentiation.

The hallmark of the B lymphocyte is the capacity to produce immunoglobulin. The loci for human immunoglobulin heavy, kappa, and lambda chain genes, have been mapped to chromosomes 14, 2, and 22, respectively.⁷⁻¹⁰ The genes coding for each immunoglobulin class are represented by a number of exons separated by noncoding regions along the chromosomes. For heavy chain genes at least four distinct elements are known, termed V (variable), D (diversity), J (joining), and C (constant) regions.¹¹ The primary event leading to expression of the gene is a somatic recombination of the germline elements such that these regions are apposed.¹² A developmental hierarchy exists such that heavy chain gene rearrangement represents the first stage of B cell commitment.¹³

Until recently, immunoglobulin gene rearrangements were considered to be restricted to normal B lymphocytes and B cell neoplasms. Demonstration of heavy chain gene rearrangements in cases of common "non-T/non-B" acute lymphoblastic leukemia (ALL),¹³ and cases of chronic myelogenous leukemia in lymphoid blast crisis¹⁴ and hairy cell leukemia^{15,16} indicate that these malignancies are of B cell origin. However, rearrangements of the heavy chain gene have also been detected in human and mouse T cell lines as well as in the leukemic cells of patients with T cell malignancies.^{12,17-19}

Heavy chain immunoglobulin gene rearrangements have been reported in one human acute myelogenous leukemia cell

line (ML), one cell line with both lymphoid and monocytoid features and a t(4;11) chromosomal rearrangement, as well as in fresh leukemic cells from three patients characterized phenotypically as acute nonlymphocytic leukemia (ANLL).^{20-22,32} Most of these cases had a monocytic phenotype. The finding of an irreversible stage of B cell commitment in some non-B cell neoplasms is surprising. Moreover, it casts doubt on the concept of lineage fidelity in leukemic blasts, and suggests instead that, in some cases of leukemia, transformation occurred in a progenitor cell capable of both B cell and myeloid differentiation, or that abnormal differentiation may include some switching between cell lineages.

To investigate this phenomenon, we studied leukemic cells from 33 adult patients with active acute myelomonocytic leukemia (AMMoL) or acute monoblastic leukemia (AMoL; FAB types M4 and M5)²² for the presence of immunoglobulin heavy chain gene rearrangements. This patient population was well characterized phenotypically and cytogenetically. We report that the immunoglobulin genes retained germline configuration in all cases.

MATERIALS AND METHODS

For cytogenetic analysis, fresh leukemic cell specimens were obtained from peripheral blood buffy coat or bone marrow from patients at the University of Chicago (23 patients) and from other institutions (10 patients). These patients all had active ANLL that

had been classified as FAB type M4 or M5 by morphology and by cytochemical reactions according to established criteria.²³

Cytogenetic analysis was performed on cells obtained at the time of diagnosis or at clinical relapse as previously described.^{24,25} Metaphase chromosomes were analyzed using trypsin-Giemsa or quinacrine fluorescence banding techniques. Chromosome abnormalities were described according to the International System for Human Cytogenetic Nomenclature (1978).²⁶ An abnormal clone was defined by the detection of at least two pseudo-diploid or hyperdiploid cells, or at least 3 hypodiploid cells with identical chromosomal abnormalities.

High molecular weight DNA extracted from leukemic cell specimens that had been stored at -70°C was digested with the restriction enzyme Bam HI. The products were size-fractionated by electrophoresis in 0.8% agarose gels, and the DNA fragments were then transferred to activated nylon membranes (Gene Screen Plus, New England Nuclear, Boston, Mass) by the technique of Southern.²⁷ Membranes were hybridized as described previously,²⁸ with nick-translated ³²P-radiolabeled probes cloned in pBR 322 plasmids. Probes used recognizing the joining region of the immunoglobulin heavy chain gene (J_H -region) have been previously described.¹⁶ After

extensive washing of filters, autoradiography was performed against a sheet of x-ray film using a dual intensifying screen for 1 to 2 weeks at -70°C .

RESULTS

A total of 80 adult patients with a diagnosis of M4 or M5 ANLL were karyotyped at the University of Chicago between 1981 and 1985. Thirty-three of these patients had adequate numbers of leukemic cells frozen for DNA analysis and these constitute the study population. The median age of this group was 50 years (range 18 to 85 years). Twenty-three patients were characterized as AMoL (FAB type M4) including one patient with ANLL following refractory anemia. This patient (no. 214—see Table 1) had received low-dose cytosine arabinoside prior to the diagnosis of ANLL. Ten patients were characterized as AMoL (FAB type M5) including one patient who developed ANLL following chemotherapy for lung carcinoma. Twenty-eight patients had newly diagnosed ANLL and 5 patients were

*Therapy-related leukemia.

studied at the time of relapse. Leukemic cells constituted 48% to 99% of nucleated cells in the specimens obtained, as assessed by morphology (peripheral blood in 11, bone marrow in 22 patients).

The karyotypic abnormalities identified in these patients were consistent with those generally seen in these types of leukemia (see Tables 1 and 2).²⁹ Specifically, the inv(16) or t(16;16) that has been associated with AMMoL^{25,29,30} was observed in 9 patients, and the t(9;11), a rearrangement commonly seen in AMoL, was noted in 2 patients. Chromosomal anomalies seen in other types of ANLL, such as the t(8;21) and t(15;17) in M2 and M3, respectively, were not seen in this group. One patient (no. 188) who had a hyperdiploid clone with 57 chromosomes had an extra chromosome 14; otherwise no abnormalities involving chromosome 14 (site of the heavy chain gene) were found. This observation is not surprising since nonrandom abnormalities of chromosome 14 have not been reported in ANLL. A gain of chromosome 22 was observed in 3 patients. In each case this abnormality was associated with an inv(16) or a t(16;16), a phenomenon that has been reported previously.²⁹ A single patient (no. 148) had a rearrangement involving chromosome 2; however, this rearrangement involved a breakpoint in band p25, a site that is distal to the immunoglobulin light chain locus at p11-p13. Only 9 patients failed to show a clonal abnormality.

All 33 cases were analyzed for immunoglobulin gene rearrangements. In each case DNA was retained in the germline configuration (single 18 kilobase fragment) with no evidence of rearrangements (see Fig 1).

DISCUSSION

In our study, all of the adult patients with the M4 or M5 subtype of ANLL clearly retained the immunoglobulin heavy chain gene in its germline configuration. We decided to investigate the monocytic and myelomonocytic subgroups, since immunoglobulin gene rearrangements in ANLL seem to be more common in these subgroups. All our patients were well characterized as M4 and M5 and no patients had ambiguous markers or lymphoid phenotypes. These findings

Fig 1. (A) Southern blot analysis of BamHI digests from leukemic cells of 7 patients with acute myelomonocytic (M4) or acute monoblastic (M5) leukemia, and controls (C, human placental DNA, CML, peripheral leukocyte DNA from a patient with chronic myeloid leukemia, HCL, peripheral leukocyte DNA from a patient with hairy cell leukemia). Blots were hybridized with a J_H -specific probe. All patients with ANLL retained the germline 18kb fragment. (B) Rearranged J_H genes from a patient with hairy cell leukemia are shown as a positive control. Lane 1: fragment size markers at 23, 9.4, and 6.6 kilobases. (The faint band seen at 10.5 kb in all but one lane is artifactual, shown by rehybridization to be contaminating plasmid DNA—data not shown.)

are in contrast to two recent series; Rovigatti et al²² demonstrated a $C\mu$ segment rearrangement in 2 of 14 samples examined from children with ANLL, and Ha et al²⁰ found a rearrangement in one adolescent patient classified as FAB type M1, but only germline configuration of immunoglobulin genes in 8 other children and 10 adults with ANLL.

Of six myeloid cell lines studied to date, only one (ML) has shown a $C\mu$ rearrangement; HL-60, K562, U937, THP1, and KG-1 show no such rearrangement.²⁰⁻²² The cell line established from a 32-year-old leukemic patient with a t(4;11) translocation also had a $C\mu$ rearrangement.³² This information is difficult to interpret because this cell line simultaneously displays lymphoid and monocytic features. Patients with this karyotype may be diagnosed as acute lymphoblastic, acute myelomonocytic, or biphenotypic leukemia.^{31,32}

In a variety of hematopoietic malignancies that have nonspecific surface markers, the presence of rearrangement

of immunoglobulin genes from the germline configuration is considered a marker of clonal B cell differentiation.¹³⁻¹⁶ However the observations of such rearrangements in a few cases of myeloid leukemia have led to the suggestion that the initial event in immunoglobulin gene organization occurs during an early stage of hematopoietic cell development, at a time when the cells are not restricted to B lineage development, but may differentiate along more than one pathway.²⁰ This concept is supported by the demonstration of heavy chain rearrangements in an occasional T cell neoplasm.^{13,17-19}

All of these exceptions raise questions regarding the concept of lineage fidelity in acute leukemia. In contrast, our findings support the concept of lineage fidelity, and suggest instead that true interlineage infidelity, myeloid to lymphoid, is either an extremely uncommon occurrence in adult ANLL, or that its appearance is confined to childhood ANLL.

Treatment of Preleukemic Syndromes With Marrow Transplantation

By Frederick R. Appelbaum, Rainer Storb, Robert E. Ramberg, Howard M. Shulman, C. Dean Buckner, Reginald A. Clift, H. Joachim Deeg, Alexander Fefer, Jean Sanders, Steven Self, Jack Singer, Patricia Stewart, Keith Sullivan, Robert Witherspoon, and E. Donnell Thomas

Thirty patients with advanced preleukemic syndromes were treated with marrow transplantation. Most cases were diagnosed by the presence of peripheral pancytopenia and a diagnostic marrow examination but in 6 of the 30 patients pretransplant chromosome studies were instrumental in establishing the diagnosis. Three patients prepared for transplantation with cyclophosphamide alone recurred with their disease within 6 months of transplantation. The other 27 patients were treated with cyclophosphamide and total body irradiation. Twenty of these 27 patients had preleukemia not associated with prior therapy or severe marrow fibrosis. Thirteen of these 20 are alive and well 9 to 56 months from transplant and 7 died, 4 of interstitial pneumonia, 2 of candida septicemia, and 1 of

disseminated zoster. There have been no disease recurrences in this group. The remaining preleukemic patients, which include 3 patients transplanted for preleukemia secondary to prior therapy and 4 patients transplanted for preleukemia associated with severe marrow fibrosis, have all died. Major problems in these patients included disease recurrence (2 cases) and, in those with severe marrow fibrosis, graft failure (2 cases). These results suggest that for patients with life-threatening pancytopenia due to spontaneous preleukemia without severe marrow fibrosis, marrow transplantation can prolong disease-free survival and may result in cure of the disease.

©1987 by Grune & Stratton, Inc.

PRELEUKEMIA describes a group of bone marrow disorders characterized by abnormal maturation of hematopoietic cells and the development of peripheral blood cytopenia.¹⁻⁶ Although the clinical course of preleukemia is variable, as many as 75% of patients will develop acute leukemia within 24 months of diagnosis and many others die of complications related to thrombocytopenia or leukopenia before overt leukemia develops.¹⁻⁶ Unfortunately, few therapeutic options exist for the patient with preleukemia. Androgens, pyridoxine, prednisone, and standard cytotoxic therapy are rarely of benefit.⁷⁻⁹ More recently the use of low-dose cytarabine has been shown to result in meaningful clinical responses in some patients.¹⁰⁻¹² However, these responses have almost always been incomplete and temporary with no suggestion of curative potential.

Marrow transplantation is an effective therapy for a number of malignant and nonmalignant marrow diseases. We therefore initiated a clinical trial of the use of marrow transplantation in patients with preleukemia and life-threatening cytopenia. Results in ten cases have been reported.¹³ Thirty patients have now been treated. In this report the toxicities and therapeutic results of marrow transplantation for preleukemia are described.

PATIENTS AND METHODS

Thirty consecutive patients with preleukemia were treated between May 1977 and December 1985. In this study we included as "preleukemic" patients with pancytopenia and the presence of myelodysplasia on marrow examination, patients with aplastic marrows and a clonal cytogenetic abnormality of a type associated with hematologic malignancies, or patients with otherwise unexplained myelofibrosis. Table 1 shows the clinical characteristics of the patients. Ages ranged from 4 to 54 years (median 24 years) with 17 males and 13 females. In 3 patients (UPN 2798, 2799, and 2813) preleukemia was apparently therapy related, in 3 cases (UPN 2173, 2855, and 1763) preleukemia occurred in patients with Fanconi's anemia, and one patient (UPN 1694) had a family history of preleukemia. No cause was identified in the other 23 cases. The median duration of disease from diagnosis to transplantation was 12 months and ranged from 2 to 180 months. All patients received transfusion support prior to referral and 19 had received prior therapy, the most common forms of therapy being steroids (16 patients), androgens (6 patients), and low-dose cytarabine (4 patients). At the time of referral for transplantation all patients required red cell transfusion support, 26 required platelet transfusions, and 25 had a granulocyte count of less than 1,000/cu mm. Peripheral blood and marrow samples were reviewed and classified, when possible, according to the proposals of the French-American-British (FAB) cooperative group.¹⁴ Degree of marrow fibrosis was graded according to the criteria of Bauermeister.¹⁵ Twenty-one patients had disease that could be classified as myelodysplastic according to the proposed FAB schema including 9 patients with refractory anemia and 12 patients with refractory anemia with excess blasts. Six patients had aplastic marrows but a clonal cytogenetic abnormality. Two patients had unexplained myelofibrosis. A final patient had a normal appearing marrow but severe pancytopenia and trisomy 8.

Marrow samples were processed for chromosome analysis after 1.5 and 24 hours in culture without added mitogens. In 3 patients (UPN 2208, 2254, and 2813) marrow either could not be aspirated or no metaphases were present for analysis. Chromosome banding was done using quinacrine mustard for Q bands.

Details of the transplant procedure are presented in Table 2. Histocompatibility between donor and recipient was determined by HLA typing and mixed leukocyte culture tests. In 24 cases the donor was an HLA-identical sibling, in 1 case an HLA phenotypically matched father, and in 5 cases a son or sibling mismatched for 1 (2 cases) or 2 (3 cases) antigens.

The technique of marrow transplantation has been described.¹⁶

†Patients treated for a prior malignancy; UPN 2798 with busulfan; UPN 2799 and 2813 with nitrogen mustard, vincristine, prednisone, procarbazine, and irradiation.

‡Presence (+) or absence (—) pretransplant of antibody to cytomegalovirus.

The preparative regimens used prior to transplantation were those we have used for treatment of aplastic anemia (UPN 691, 1042, and 1442) or acute leukemia (the remaining 27 patients).^{17,18} All patients received posttransplant immunosuppression with either methotrexate (4 cases), cyclosporine (1 case), or a combination of the two (25 cases) in an effort to diminish or prevent graft-v-host disease (GVHD).^{19,20}

Patients were also entered on other protocols involving laminar air flow isolation and prophylactic systemic antibiotics. All risks of the treatment protocol were fully explained to patients, donors, and relatives. Informed consent was obtained using forms approved by the Investigational Review Board of the Fred Hutchinson Cancer Research Center. Data were analyzed as of July 1, 1986.

RESULTS

The results are summarized in Table 2. Three patients (UPN 691, 1042, and 1442) were prepared for transplantation with cyclophosphamide alone and, as previously reported, in all three cases there was evidence of either persistence or recurrence of the abnormal cell clone within 6 months of transplantation. Despite further chemotherapy (1 patient) or second marrow transplants (2 patients), all three patients died within 9 months of initial transplant.

All other patients were prepared for transplantation with a regimen consisting of cyclophosphamide and total body

irradiation. Three patients (UPN 2798, 2799, and 2813) were transplanted for therapy-related preleukemia, 2 after chemoradiotherapy for Hodgkin's disease, and 1 after prolonged busulfan therapy for polycythemia vera. All three died within 3 months of transplant, one of persistent disease, one of septic shock, and one of venoocclusive disease of the liver and candida septicemia. Four patients were transplanted for preleukemic syndromes characterized by extensive marrow fibrosis. None of these 4 survive with one patient dying of recurrent disease, 2 with graft failure associated with either bleeding or infection, and one of idiopathic interstitial pneumonia. Twenty patients were transplanted for preleukemia which was neither therapy related nor associated with extensive marrow fibrosis. Thirteen of these 20 patients are alive without either clinical or cytogenetic evidence of disease from 9 to 56 months after transplant. The seven patients who failed therapy included 4 cases of interstitial pneumonia (3 idiopathic and one associated with cytomegalovirus; CMV), 2 cases of candida septicemia, and one case of disseminated herpes zoster infection. None of the 20 patients suffered a recurrence of their disease.

In addition to the apparently important influences of the preparative regimen, etiology of disease, and presence of marrow fibrosis, patient age seemed to influence survival

Abbreviations: UPN, unique patient number; CY, cyclophosphamide; TBI, total body irradiation; GVHD, graft versus host disease; MTX, methotrexate; CSP, cyclosporine; IP, interstitial pneumonia; CMV, cytomegalovirus; VOD, venoocclusive disease of the liver.

($P = .047$, log rank test). We could detect no influence of disease duration, marrow cellularity, marrow morphology (except for extensive fibrosis), or cytogenetic findings on treatment outcome. Of 6 patients receiving grafts from other than genotypically matched donors, two remain alive. Three patients (UPN 2173, 2855, and 1763) had Fanconi's anemia preceding the development of preleukemia. One of these (UPN 1763) tolerated the transplant procedure well while the other 2 developed early severe toxicity and died of interstitial pneumonia.

The health of the 13 disease-free survivors is excellent. All have normal hematologic function and 12 of the 13 are off all medications with Karnofsky scores of 90% to 100%. One patient has developed bronchial asthma posttransplant without other evidence of chronic graft-v-host disease. He requires no immunosuppressive therapy.

DISCUSSION

Despite recent advances in the management of patients with preleukemic syndromes, in particular the use of low-dose cytarabine, patients with preleukemia are generally considered to be incurable and most of these patients die with bleeding, infection, or acute leukemia. The success of high-dose chemotherapy or chemoradiotherapy followed by marrow transplantation as treatment for various marrow disorders

prompted us to study this approach in patients with preleukemic syndromes.

The first 3 patients were given cyclophosphamide alone as a preparative regimen, similar to the way in which patients with aplastic anemia are prepared for transplantation. Although all three demonstrated evidence of engraftment of donor marrow, in all three the malignant clone recurred suggesting that cyclophosphamide alone, or combined with any allogeneic reactivity of the engrafted marrow, is inadequate to eradicate the abnormal cell population. Accordingly, subsequent patients were treated with cyclophosphamide and TBI.

Results obtained with a combination of cyclophosphamide and TBI in patients with preleukemia unassociated with previous therapy or severe marrow fibrosis were encouraging. Thirteen of 20 patients are alive in complete remission up to 56 months from therapy. Importantly, there has not been a single episode of disease recurrence in this group. Although continued follow-up is necessary, this result suggests that the preparative regimen used, cyclophosphamide 60 mg/kg for two days followed by 200 cGy/day of TBI for six days, is adequate to eradicate the abnormal cell population. The major reason for treatment failure was interstitial pneumonia in 4 patients, in one case associated with CMV and in 3 cases idiopathic. These 4 patients included 2 with a history of Fanconi's anemia and 2 transplanted from mis-

matched donors. Since recurrent disease has not been a major problem and since irradiation presumably contributed to the observed toxicities, the use of lower doses of TBI or lung shielding might be considered in patients undergoing transplantation for preleukemia.

Results in the small group of patients with preleukemia secondary to previous therapy were less encouraging. One patient never cleared his abnormal cell population and the other 2 died of transplant-related complications. This unfavorable experience is apparently not universal. Gyger et al reported a 22-year old man who developed preleukemia following chemoradiotherapy for Hodgkin's disease who received an HLA-identical marrow graft from his sister following treatment with busulfan and cyclophosphamide. He was reported to be alive in remission 311 days posttransplant.²¹

Results in the 4 patients transplanted for preleukemia associated with extensive marrow fibrosis were discouraging. None of these patients is alive, one having relapsed and 3 having died of transplanted-related complications. Further, in 3 of these 4 patients normal peripheral blood counts were never achieved despite evidence for lymphoid engraftment and in 2 of these 3, pancytopenia was the cause of death. There are several case reports that demonstrate that engraftment can be achieved in some patients with severe marrow fibrosis.²²⁻²⁶ But, as case reports, these studies did not compare the outcome of transplantation in patients with and

without marrow fibrosis. The question of the effect of severe marrow fibrosis on engraftment prompted us to review our wider experience with transplantation in patients with marrow fibrosis of any etiology. As recently reported by Rajantie et al, patients transplanted for preleukemia, chronic myelogenous leukemia, or acute leukemia with coexistent extensive marrow fibrosis frequently have difficulty with engraftment as evidenced by a graft failure rate of 33% and slower myeloid and platelet engraftment in those who do engraft when compared to age- and disease-matched control patients with little or no fibrosis.²⁷

The experience reported here emphasizes the importance of marrow cytogenetic results in deciding on treatment of patients with pancytopenia. Six of the 30 patients described here were thought on initial morphologic examination of the marrow to have aplastic anemia. In each case marrow cytogenetics showed a clonal chromosomal abnormality establishing the diagnosis of preleukemia, including 3 cases of monosomy 7, one case of trisomy 8, one case with 46,XX,ins(3;3)(q26;q21q26), and one case with 48XY,-7,+8,+21,+22.

Patients with preleukemia and life-threatening pancytopenia, in general, do poorly. The results reported here, particularly in those patients with de novo preleukemia without severe marrow fibrosis, suggest that if an appropriate donor is available, marrow transplantation should be strongly considered.

Cytogenetic and Histologic Correlations in Malignant Lymphoma

By Prasad R.K. Koduru, Daniel A. Filippa, Mark E. Richardson, Suresh C. Jhanwar, Seeta R. Chaganti, Benjamin Koziner, Bayard D. Clarkson, Philip H. Lieberman, and R.S.K. Chaganti

Although a number of studies have indicated correlations between histologic subtypes of tumors and certain nonrandom chromosome changes, cytogenetic studies of lymphoma are in an early stage compared to those of leukemia. No comprehensive analysis of available data has so far been attempted in the literature either. Here we present an analysis of chromosome changes and their correlation with subtypes of lymphoma studied by conventional histology and cell surface markers, as observed in two sets of data: (1) a group of 65 karyotypically abnormal tumors sequentially ascertained and studied by us during the period January 1, 1984 to April 30, 1985, and (2) a larger data set derived by combining our data with those from two published series from the University of Minnesota that are comparable to our data. These combined data, which

comprise the largest data set on the cytogenetics of lymphomas assembled so far, enabled a comprehensive analysis of correlation between chromosome change and tumor histology and the patterns of chromosome instability in these tumors. We found several significant associations, some previously described and others now recognized, between nonrandom chromosome gains, breaks, translocations, and deletions and histologic subtypes of tumors that characterize lymphomas. The data indicate that finding of chromosome breaks at certain sites (eg, 8q24, 14q32, 18q21) is of diagnostic value in dealing with cases of unusual lymphoma. Furthermore, nonrandom chromosome breakage exhibited three distinct patterns that reflected three levels of etiologically relevant genetic change.

© 1987 by Grune & Stratton, Inc.

HISTOLOGIC and immunologic studies of malignant lymphoma have led to a number of systems of classifications that have attempted to define subgroups based on biological relatedness or clinical significance.¹⁻⁴ Recent molecular studies of Burkitt's lymphoma and chronic myelogenous leukemia have shown that chromosome translocations play an important role in the development of neoplasia by bringing about deregulation of the genes involved in rearrangements.^{5,6} Cytogenetic studies of leukemia further have established that specific chromosome abnormalities are diagnostic and prognostic indicators.^{7,8} The clinical significance of cytogenetic changes in lymphomas is less clear⁹⁻¹² compared to leukemias where chromosome analysis is now performed as part of the clinical evaluation of patients. A number of recent studies however have demonstrated that recurring translocations t(14;18)(q32;q21) and t(8;14)(q24;q32) and the recurring deletion del(6q) are associated with certain histologic subtypes of lymphomas.¹³⁻¹⁶

We have been conducting a prospective study of correlations between chromosome changes, histology, and immunological markers in tumors from all patients with a presumptive diagnosis of lymphoma seen by the Hematology/Lymphoma Service of Memorial Sloan-Kettering Cancer Center (MSKCC) since January 1, 1984. Although, as mentioned above, previous studies have addressed translocations and deletions associated with non-Hodgkin's lymphoma (NHL), a comprehensive review of cytogenetic abnormalities associated with lymphoma has been lacking. By utilizing a combination of our data with that reported by two groups from the University of Minnesota,¹³⁻¹⁶ each of which included more than 50 karyotypically abnormal tumors classified by the Working Formulation (WF; Table 1), we have been able to assemble the largest data set examined so far and undertake such a review. Our analysis confirms the previously reported associations as well as establishes new correlations. In addition, we have been able to define classes of chromosome instability in lymphoma that indicate specific mechanisms of gene perturbation that are of possible significance in lymphoma development.

MATERIALS AND METHODS

Patient population and tumor material. During the study period we have analyzed 110 histologically confirmed lymphomas removed from 110 patients whose ages ranged from 7 to 80 years (mean 50 years). Of these, 58 were males and 52 were females. In 79 patients the tumor was studied at primary diagnosis, while in 25 it was studied during relapse following previous chemotherapy or radiation therapy. Previous treatment history was unknown in the remaining 6 patients. In each of three patients, two separate specimens were received yielding a total sample of 113 specimens. Involved tissues included lymph nodes in 59, lymph node and pleural fluid in one, spleen in 16, nonlymphoid tissues (fibrous tissue, muscle, lung, etc) in 22, bone marrow in 13, and ascites alone in one patient. A piece of each tumor received in Pathology was submitted for independent studies of histology, immunological markers, and cytogenetics; in addition, a small piece was frozen immediately and stored in liquid nitrogen for molecular studies. No criteria other than availability of tissue were applied in selecting patients for study. Because of this, 24 benign lymphadenopathies and 13 Hodgkin's disease lymph nodes also were examined during this period. The data pertaining to these specimens are not discussed here. In all cases, the tissue was processed within one hour of removal from the patient. All tissues used in this study were submitted to the laboratory for diagnostic evaluation. As such, they were removed from the patients

after obtaining informed consent for evaluation at the time of admission to Memorial Hospital.

Histology and immunological markers. Histologic preparations were made from solid tumor tissue usually fixed in B3 and stained with hematoxylin and eosin using standard methods. Lymphomas were classified according to the WF, Rappaport, Lukes-Collins, and Kiel systems.¹⁻⁴ Bone marrow and effusion specimens were examined only to ascertain the presence of lymphoma. Bone marrow biopsies were embedded in Epon plastic and stained with Giemsa. The WF classification was followed in describing tumors in this paper in order to facilitate comparison of our data with those from other published series.¹³⁻¹⁶ In the text we have referred to the different lymphoma subsets by their abbreviations as indicated in Table 1. Cell surface phenotypes were studied in cell suspensions of solid tumors (lymph node, spleen, soft tissues) while surface as well as cytoplasmic phenotypes were studied on bone marrow tumors. The methods used for these studies included study of conventional markers for lymphoid cell subpopulations (IgG-FC, C₃ receptors, heavy and light chain immunoglobulins, and rosetting with sheep and mouse red cells) as well as typing with a panel of monoclonal antibodies (OK-T1, OK-T3, OK-T4, OK-T6, OK-T8, OK-T11, J-5, OK-Ia, B1, B2, and OK-M1).

Cytogenetics. The tumor specimen was minced into a single-cell suspension immediately upon receipt in the laboratory under sterile conditions in prewarmed RPMI 1640 medium. The cells were pelleted by centrifugation at 400 rpm for ten minutes, and resuspended in the same medium supplemented with 20% heat-inactivated fetal calf serum, 1% penicillin-streptomycin, and 1% L-glutamine. Cell viability was determined by trypan blue exclusion, and the cell concentration was adjusted to approximately 10⁶ living cells/mL. A direct harvest was made from one 10 mL cell suspension after exposure to 0.05 µg/mL colcemid for ½ hour at 37 °C. A second 10 mL cell suspension was incubated at 37 °C overnight with 0.025 µg/mL colcemid and harvested, and a third 10 mL cell suspension was incubated overnight at 37 °C, then exposed to 0.05 µg/mL colcemid for one hour and harvested. Cell harvesting was done following procedures used for chromosome preparations from blood lymphocytes. Quinacrine banding was employed throughout in karyotyping. For each patient with a successful culture, 15 to 30 cells were analyzed under the microscope for changes in chromosome number and structure. This was followed by analysis of photographic prints of at least five cells in the case of tumors with a single abnormal clone and ten cells in the case of tumors with more than one abnormal clone; three formal karyotypes were prepared for each clone. The karyotypes were described according to ISCN.¹⁷ (The detailed tabulation of tumor histology, cell surface markers, and karyotypes of all tumors studied by us is not published here but is available upon request from R.S.K. Chaganti).

Statistical analysis of data. We enumerated all identified chromosome abnormalities (gains and losses of individual chromosomes, translocations and deletions, and breakpoints of structural altera-

tions) from all tumor karyotypes from our data as well as from the combined data (CD). We tested for the nonrandomness of numerical and structural chromosome changes using the computer program for statistical analysis of chromosome changes written by Brodeur et al.¹⁸ This program tests the significance of observed deviation from the expected on two assumptions: (1) in the generation of numerical alterations all chromosomes have the same probability of undergoing nondisjunction, and (2) in the generation of structural alterations the frequency of chromosome breaks occurs proportional to the length of the chromosome arm. Conventional 2 × 2 chi-square analysis was employed to compare the frequency of occurrence of chromosome abnormalities between different histologic subtypes.¹⁹ The latter method has been used by Levine et al¹⁶ in their analysis of chromosome changes in lymphomas.

RESULTS

Histologic classification of part of the same tissue specimen that was used for cytogenetic and immunological marker studies was accomplished in 98 cases that presented as solid tumors. Cytogenetic analysis was performed on bone marrow and ascites specimens in only 14 cases. These were considered unclassified lymphoma for the purpose of this study. Cell surface markers established B cell type in 74 (86%) tumors, T cell type in four (4.7%), and null cell type in six (7%); the results were inconclusive in two (2.3%) cases. Marker studies were not performed in the remaining 27 tumors. IgM was expressed by 45 (60.1%) and IgG by 16 (21.6%) B cell tumors. More than one heavy chain was expressed in seven tumors. The kappa and lambda light chain markers were expressed nearly equally (36 and 30 tumors, respectively). The four T cell tumors were of postthymic (or peripheral T cell type) and histologically identified as large cell or immunoblastic types. No case of lymphoblastic T cell lymphomas were encountered in this study.

In our series, 77% of the specimens yielded sufficient numbers of analyzable metaphases, a cytogenetic success rate that is comparable to the 68% and 65% reported by Bloomfield et al¹⁵ and Kaneko et al,¹² respectively, although Yunis et al^{13,14} reported a 93% to 95% success rate in their series. Among the 87 successfully karyotyped specimens, five follicular and 16 diffuse tumors (24% of total successful cases) showed only normal karyotypes. Therefore these were considered as the karyotypes of the proliferating reactive cells in the malignant tumor and were not included in the statistical analysis of the data. The remaining 66 specimens (65 tumors) showed clonal karyotypic abnormalities. A mixture of normal and clonally abnormal cells was present in five follicular and 12 diffuse tumors. More than one abnor-

Fig 1. Losses and gains of chromosomes in malignant lymphoma. While none of the losses was statistically significant, gains of chromosomes 5, 7, and 12 in the MSKCC data and gains of chromosomes 3, 7, and 12 in the CD were statistically significant. □, Combined data; ■, MSKCC data.

mal clone was seen in two follicular and four diffuse tumors. Tumors from treated and untreated patients did not show significant differences in chromosome abnormalities. Therefore, the data are presented together. For the analysis of correlation between histology and cytogenetics, the 51 tumors for which both sets of data were available only were considered while chromosome instability was analyzed from the entire dataset.

Numerical changes. Although loss of different chromosomes was noted in 14 tumors in our data, a consistent correlation with histology was not seen. With regard to gains, 29 tumors showed trisomy of 21 different autosomes (Fig 1). Trisomy of chromosomes 7, 5, 11, and 12 were most frequent, and showed strong histologic correlations. Of 19 cases of LC-D, six showed trisomy 7 and five showed trisomy 12. Of the nine cases of diffuse large cleaved cell lymphoma (LCC-D), a subgroup of LC-D, three showed trisomy 11, and of the 10 cases of diffuse large noncleaved cell lymphoma (LNCC-D), another subgroup of LC-D, three showed trisomy of chromosome 5.

Among the tumors in the CD, significant deviation from

expected was found in the case of trisomy of chromosomes 3 in Mx-D (5/20), 5 in Imb (3/11), 7 in LC-F (7/20) and LC-D (13/54), and 12 in SmLy (13/41) (Table 2) when tested by the method of Brodeur et al.¹⁸ When the incidence of trisomy of given chromosomes in given histologic subtypes was compared with that in the entire CD lymphoma sample using the chi-square method,¹⁹ we observed a significant excess of chromosome 8 in Mx-F (4/16) and chromosome 21 in LC-D (9/54) as did Levine et al in their series.¹⁶ We additionally found a high incidence of trisomy 4 and X in LC-D (3/54 and 8/54, respectively), 5 in Imb (3/11), and 7 in LC-F (7/20) and LC-D (13/54).

Translocations. We identified 74 translocations in the 65 tumors analyzed. Of these, 42 (56.8%) belonged to three recurrent types, namely, t(8;14)(q24;q32) (10 cases), t(11;14)(q13;q32) (three cases), and t(14;18)(q32;q21) (29 cases). The remaining 32 (43.2%) were unique translocations (Table 3). The translocations t(14;18) and t(8;14) showed strong correlation with the grade of lymphoma; the former was seen in 76.5% (13/17) of low-grade tumors, 33.3% (9/27) of intermediate-grade tumors, and 14.3% (1/7) of high-grade tumors. Of the 8 intermediate-grade diffuse tumors that showed t(14;18); five were relapse specimens from patients in whom a previous biopsy had established the diagnosis of poorly differentiated lymphocytic lymphoma. The single high-grade tumor in our series with t(14;18) was a relapse tumor previously classified as LC-D. Interestingly, this tumor also showed t(8;22)(q24;q11), which is associated with high-grade tumors. In contrast, t(8;14) was absent in low-grade tumors and was present in 18.5% (5/27) of intermediate-grade and 42.9% (3/7) of high-grade tumors. Impressive associations between specific translocations and tumor subtypes were seen in the case of t(14;18) with SCC-F (9/10) and Mx-F (4/4), and t(8;14) with SNCC (3/3). We saw only three cases of t(11;14); two of these were in LNCC-D and one was in SCC-F (Table 3).

In the CD, t(14;18) was common in low- (49.6%) and intermediate- (24.0%) grade tumors and rare in high-grade tumors (3.6%; Table 3). Its incidence in the histologic subtypes was similar to that encountered in our series. It was absent from SmLy and was seen in 71% of SCC-F and 93.8% of Mx-F. Of 16 diffuse tumors in the CD that exhibited t(14;18), nine (56.3%) were reported to have evolved from a previous nodular lymphoma.

Table 2. Summary of Recurring Cytogenetic Changes in Histologic Subtypes of Malignant Lymphoma—CD*

Histologic Subtype	Tumors Studied (no.)	Cytogenetic Change			
		Trisomy	Translocation	Deletion	Breaks
SmLy	41	12	—	11q	14q
SCC-F	62	—	t(14;18)	6q	14q, 18q
Mx-F	16	8	t(14;18)	2q	2p, 14q, 18q
LC-F	20	7	t(14;18)	—	7p, 13q, 14q, 17q, 18q
SCC-D	6	—	—	8p, 20q	—
Mx-D	20	3	—	—	9p, 19q
LC-D	54	4, 7, 21, X	—	6q	1q, 4q, 6q, 9q, 14q, 18q
SNCC	12	—	t(8;14)	—	8q, 14q
Imb	11	5	—	3p, 5q, 6q	5p, 5q, 16q, 19p
Lyb	5	—	—	—	—

Table 3. Frequency of Different Translocations in Histologic Subtypes of Malignant Lymphoma: Comparison of MSKCC Data With CD*

Histologic Subtype	Recurring Translocation						Unique Translocations		Total	
	t(8;14) (q24;q32)		t(11;14) (q13;q32)		t(14;18) (q32;q21)		MSKCC	CD	MSKCC	CD
	MSKCC	CD	MSKCC	CD	MSKCC	CD				
SmLy	0	1	0	4	0	0	0	21	0	26
SCC-F	0	0	1	1	9	44	3	38	13	83
Mx-F	0	0	0	0	4	15	0	16	4	31
LC-F	1	1	0	0	1	8	1	23	3	32
SCC-D	0	0	0	0	2	2	0	1	2	3
Mx-D	0	0	0	0	0	0	1	27	1	27
LC-D	4	9	2	4	6	14	15	58	29	85
SNCC	3	10	0	0	0	0	3	4	6	14
Imb	0	2	0	0	1	1	2	10	3	13
Lyb	0	0	0	0	0	0	0	5	0	5
Unclassified	2	2	0	0	6	7	7	9	13	18
Total	10	25	3	9	29	91	32	212	74	337

*Only translocations for which all breakpoints have been identified are included in the analysis.

In the CD, t(8;14)(q24;q32) similarly was the most common translocation in high-grade tumors (42.9%) and less so in intermediate-grade (10.0%). In the CD, t(8;14)(q24;q32) showed an 83.3% association with SNCC lymphomas. The third recurring translocation, t(11;14)(q13;q32), was absent in high-grade tumors in the CD, but was presented in low- and intermediate-grade tumors with nearly equal frequency (4.2% and 3.7%, respectively). In addition, four other translocations recurred at least twice each in the CD, but showed no correlation with histologic subtypes. These were t(3;14)(p21;q32), t(5;14)(q23;q32), t(11;14)(q23;q32), and t(14;19)(q32;q13).^{14,16}

Chromosome 1 was one of the participants in 18/32 unique translocations in our data and was the most frequent participant in these translocations. Regions 1p31-36 and 1q21-25 exhibited clustering of translocation breaks (seven and six times, respectively). In the CD, chromosome 1 was involved in 63/413 unique translocations. Of these region 1p31-36 was involved in 21 translocations and the region 1q21-25 was involved in 17 translocations. Thus, although

chromosome 1 seemed to be less frequently involved in translocation in the CD than in our series, when translocations affected chromosome 1, the frequency with which breaks clustered in the 1p31-36 and 1q21-25 was almost as high as in our series (60% v 70%).

Deletions. We identified chromosome deletions in 29 tumors and 1p and 6q were most frequently affected (Fig 2). The histologic groups SCC-D, LC-D, and Imb were frequently affected by deletion (75%, 52.6%, and 100%, respectively). Of the four tumors with del(1p), two were LNCC-D and of the three tumors with del(3p), two were Imb.

In the CD, deletions affected all chromosomes with the exception of chromosome 21 (Fig 2). Within histologic subtypes, 6q deletions were in excess in SCC-F, LC-D, and Imb while 11q deletions were in excess in SmLy ($P < 0.05$).¹⁸

Fig 2. Deletions of chromosomes in malignant lymphoma. p and q are short and long arms, respectively. Overall, del(6q) in the MSKCC data and del(1p) and (6q) in the CD were significantly in excess. However, deletions of several chromosomes were significantly in excess in certain histologic subtypes (see text). □, Combined data; ■, MSKCC data.

Fig 3. Chromosome breaks in malignant lymphoma. p and q are short and long arms, respectively. (Centromere breaks are not shown in this diagram; they were also not included in the analysis.) While the statistical significance of breaks in the MSKCC data was not tested, in the overall CD breaks in 1p, 1q, 6q, 14q, and 18q were significant. In addition, breaks in certain chromosomes were significantly in excess in certain histologic subgroups (see text). □, Combined data; ■, MSKCC data.

When the incidence of deletions in given chromosomes in given histologic subtypes was compared with that of the same deletion in the entire CD, the following significant deviations from expected were encountered: 2q in Mx-F, 3p and 5q in Imb, 6q in LC-D, 8p and 20q in SCC-D, and 11q in SmLy ($P < 0.05$)¹⁹ (Table 2).

Chromosome instability. We identified 270 breaks associated with specific as well as nonspecific rearrangements in our series (Fig 3). In the follicular tumors 66.7% of breaks were confined to chromosome 1, 14, and 18 while in the diffuse tumors 37.9% of breaks affected these three chromosomes. Chromosome 1 showed 15.2% of all breaks with clustering in regions 1p31-36 (12/14) and 1q21-24 (18/26). The following histologic subtypes exhibited recurrent chromosome 1 breaks: SCC-F (5/10), Mx-F (2/4), LC-D (7/19), and Imb (2/3). Breaks in the 6q21-23 region occurred in LC-D (3/19). Chromosome 7 showed 10 breaks, two in the short arm and eight in the long arm. Three of the 7q breaks were in one Imb. Chromosome 8 was most frequently affected in diffuse tumors and all breaks at 8q24 resulted in t(8;14). Breaks in chromosome 11 were clustered in the 11q13 region and were frequently seen in LC-D (5/19). Chromosome 14 showed 50 breaks (18.6% of total breaks) and 47 of them were at 14q32. Band 14q22 was affected in one SmLy and band 14q24 was affected in one Imb and in one unclassified tumor. Chromosome 18 showed 35 breaks of which 32 were at 18q21, and all of these were involved in t(14;18). Breaks in chromosomes 19, 20, 22, X, and Y were infrequent, although all three breaks encountered in chromosome 22 were at 22q11.

In the CD, a total of 1,211 breaks were enumerated for analysis (Fig 3). In the follicular tumors, 51.4% of breaks were confined to chromosomes 1, 14, and 18 while in diffuse tumors, 34% of breaks affected these same chromosomes. Chromosome 1 showed 13.4% of all breaks with clustering in regions 1p31-36 (52/71) and 1q21-24 (36/85), thus reflecting the clustering of translocation breaks in these sites stated above. Overall, a significant excess ($P < 0.05$) of breaks were seen in chromosome arms 1p, 1q, 6q, 14q, 18q, and 19q. Statistically significant associations ($P < 0.05$) were noted for breaks in chromosome 1 and lymphomas showing SCC-F and LNCC-D histology, breaks at 8q24 and SNCC lymphoma, breaks at 14q32 and SCC-F, Mx-F, and SNCC lymphomas, and breaks at 18q21 and SCC-F and Mx-F lymphomas. Additional significant correlations occurred in a number of histological subtypes and these are summarized in Table 2. Breaks in a number of chromosome arms were clustered in specific band regions, eg, 1p31-36, 1q21-32, 6q21-23, 8q24, 11q13, 14q32, 18q21, and 19q13.

DISCUSSION

Our studies presented here clearly show that recurrent cytogenetic changes characterize each of the histologic subtypes of malignant lymphoma in which more than one tumor has been studied; some of these correlations were previously established^{13,16} while others are recognized here for the first time.

The data set analyzed here represents the largest group of lymphoma karyotypes assembled so far and it shows that

cytogenetic findings are of diagnostic importance in NHL of B or null cell type (Table 2). While a variety of abnormalities have been identified, most have involved breaks at a limited number of bands. The finding of breaks at certain sites (eg, 8q24, 14q32, and 18q21) in a small cell neoplasm, especially one that arises in a nonlymphoid site, indicates that the lesion most probably is a lymphoma. The most important cytogenetic abnormalities in lymphomas appear to be a group of three recurring reciprocal translocations, eight trisomies, and seven deletions. Although highly significant associations between some of the abnormalities, especially the translocations, and histologic subtypes existed, the correlations were not unique and absolute, as is the case with most other tumor-associated specific chromosome changes.^{7,8} Thus, t(14;18) was very strongly associated with low-grade lymphomas and t(8;14) was associated with high-grade lymphomas. In addition, t(14;18) also was strongly associated with a nodular histology.

We have shown that breaks occurred nonrandomly in a number of chromosomal regions. Such breaks appeared to assume three distinct but recurring patterns: (1) Breaks that generate the specific translocations that are associated with specific histologic subtypes, namely, 8q24, 11q13, 14q32, and 18q21 (Table 3). These translocations bring about the juxtaposition of the cellular oncogenes *c-myc* (8q24),²⁰ *bcl-1* (11q13),²¹ and *bcl-2* (18q21)^{22,23} with the immunoglobulin heavy chain determinant (14q32). Translocation-mediated deregulation of *c-myc* has been demonstrated^{24,25} and it is highly likely that the other two genes are similarly deregulated by the translocations. Translocations affecting these three sites together characterized 47.3% of cytogenetically abnormal tumors in the CD. Furthermore, in several tumors in this data set they represented the sole cytogenetic abnormality suggesting that the gene deregulation that these translocations bring about plays a primary role in the development of lymphoma. (2) Breaks that generate unique translocations that are not correlated with histologic subtypes (Table 3). The best examples of this class of breaks are the chromosome 1 sites 1p34-36 and 1q22-24. These translocations never were encountered as the sole chromosome abnormality but were always seen as additional abnormalities. The cellular oncogenes *c-src*²⁶ and *c-ski*²⁷ have been mapped to these two sites, respectively. Perturbations affecting these sites are common not only in lymphomas but also in tumors of diverse cell types²⁷ suggesting that deregulation of these oncogenes may be associated with nonspecific tumor progression. (3) Breaks that generate deletions of chromosomes 1p, 2q, 3p, 5q, 6q, 8p, 11q, and 20q that correlate with histologic subtypes (Table 2). Hemizygosy or homozygosity for the nondeleted chromosome followed by reduplication of the remaining chromosome has been shown to be an important genetic event in the etiology of retinoblastoma²⁸ and Wilms' tumor.²⁹ Some of the sites of recurring deletions seen in our analysis of lymphoma also are the sites of cellular oncogenes, for example, *c-src* (1p34-36) and *bcl-1* (11q13). Other sites of deletion that we identified may turn out to be the sites of important genes yet to be discovered. Hemizygosy-homozygosity of the sites may act as a step in lymphoma development. Thus, the cytogenetic analysis presented here

identified for the first time distinct levels of genetic alteration associated with lymphoma development thereby providing new leads for further molecular analysis.

Histologic parameters that relate to prognosis continue to be defined,³⁰ and may result in revision of current classification of lymphomas. The prognostic implications of cytogenetic changes in lymphoma remain largely as unanswered questions. One immediate question relates to diffuse tumors that show t(14;18). We have established that a proportion of these had a previous nodular histology. Whether diffuse lymphomas that represent transformation from a previous nodular histology would have a better prognosis than those

that lack the t(14;18) needs to be determined. As more data from prospective series such as the ones analyzed in this paper become available, further definition of the cytogenetic correlations noted here as well as recognition of new correlations can be expected.

ACKNOWLEDGMENT

We are grateful to Dr Clara D. Bloomfield for a preprint of the article by Levine et al¹⁶ that summarized the cytogenetic analysis of the series of lymphomas studied by them and to Dr Jorge J. Yunis for providing the full karyotypes of tumors reported in 1982.¹³

Identification and Characterization of a Differentiation-Specific Antigen on Normal and Malignant Murine Erythroid Cells

By E. Rena Bacon and Arthur J. Sytkowski

Rauscher murine erythroleukemia cells grow continuously in vitro and undergo terminal differentiation in response to the physiological inducer erythropoietin. In the course of this developmental process they express many erythroid-specific markers. In order to investigate the expression of cell surface determinants during Rauscher cell differentiation we generated monoclonal antibodies to uninduced cells. Using an anti-Rauscher cell monoclonal antibody, we have identified a cell surface determinant, designated ERY-1, that is present on normal murine erythroid cells.

MURINE and human erythroleukemia cell lines have been studied extensively as model systems of erythroid commitment and differentiation. The Rauscher murine erythroleukemia cell line is particularly suitable for such investigation because of the ability of these cells to differentiate in response to the physiologic inducer erythropoietin as well as to nonphysiologic inducers, eg, dimethyl sulfoxide (DMSO).^{1,2} The cell line was derived originally from Rauscher virus-infected DBA mice and was cloned to establish more homogeneous populations.² Rauscher cells resemble immature erythroblasts morphologically, and they differentiate into hemoglobin-containing erythroid cells after induction. They synthesize all three adult murine globins—alpha, beta major, and beta minor.³ Erythropoietin induction also results in increased levels of beta-adrenergic receptors⁴ and membrane spectrin (Bacon ER, unpublished observations). While the erythroid nature of Rauscher cells seems certain, the stage of differentiation of the uninduced cells relative to normal erythropoietic progenitors has not yet been determined clearly. Some experimental evidence suggests that noninduced Rauscher cells may be at a differentiation stage similar to that of the normal erythroid progenitor BFU-E. Rauscher cells growing in semisolid medium can exhibit a rather diffuse colony morphology reminiscent of the BFU-E-derived colony. Moreover, their erythropoietin dose-response relationship is remarkably similar to that of the normal mouse BFU-E.^{2,3}

In order to examine the process of Rauscher cell differentiation further, we chose to investigate changes in the expression of cell surface determinants that occur during maturation and to compare these changes to those that occur during normal erythropoiesis. Therefore, we generated monoclonal antibodies against noninduced (and thus immature) Rauscher cells. We anticipated that the antibodies would also recognize bone marrow erythroid cells, including progenitors. We describe here the identification and characterization of an erythroid-specific surface antigen, designated ERY-1, which is expressed during certain stages of maturation of normal erythroid progenitors and of Rauscher cells.

MATERIALS AND METHODS

Production of Monoclonal Antibodies

Male Lewis rats were immunized intraperitoneally with 3×10^7 Rauscher cells (clone 404) at monthly intervals. Sera from immunized rats were assayed for anti-Rauscher cell antibodies by

This determinant is apparently absent from the early progenitor BFU-E, but is present on the more mature progenitors CFU-E and CFC-E. It disappears during erythroid maturation and is absent from the mature erythrocyte. This pattern of ERY-1 expression is exhibited with remarkable fidelity during the erythropoietin-induced differentiation of Rauscher cells. Such differentiation-specific expression of the ERY-1 determinant suggests that it may play a functional role in erythropoiesis.

enzyme-linked immunosorbent assay (ELISA; see below), and an animal with a high anti-Rauscher cell antibody titer was identified. Four days prior to the fusion, the animal selected was boosted intravenously with 5×10^7 cells. At the time of the fusion the animal was killed by CO₂ asphyxiation, and the spleen was removed. The fusion protocol was modified from the method of Kennett.⁵ Briefly, 7.5×10^7 spleen cells and 1.5×10^7 P3X63Ag8653 myeloma cells (Institute for Medical Research, Camden, NJ) were fused in the presence of 0.3 mL of 30% polyethylene glycol 1500 (PEG; BDH, Carle Place, NY). The cells were incubated at 37 °C for two minutes and then centrifuged at $260 \times g$ at 25 °C for six minutes. The supernatant was aspirated, and the cell pellet was diluted slowly with 30 mL of HY-HT medium (70% Dulbecco's MEM, 20% fetal calf serum, 10% NCTC-109 [GIBCO, Grand Island, NY], supplemented with 1.6×10^{-5} mol/L glucose, 2 mmol/L glutamine, 1 mmol/L oxaloacetic acid, 0.5 mmol/L pyruvic acid, 0.2 U/mL insulin, 1×10^{-4} mol/L hypoxanthine, 1.6×10^{-5} mol/L thymidine, and 2.5×10^{-5} mol/L 2-mercaptoethanol [Sigma, St Louis, Mo]). The cells were incubated overnight in a 150 mm plastic petri dish in 10% CO₂ at 37 °C. The next day, the cells were centrifuged and resuspended in 30 mL HY-HT medium containing 4×10^{-6} mol/L aminopterin (HAT medium). The cells were plated into six 96 well Costar (Cambridge, MA) microculture dishes on a feeder layer of human fibroblasts and incubated in a humidified incubator in 10% CO₂ at 37 °C. The cells were fed weekly with 50 uL of HAT medium per well. The supernatants from the wells containing macroscopic hybridoma colonies were screened by ELISA for antibody to Rauscher cells, to syngeneic adult murine liver cells, and to thymocytes. Colonies whose supernatants contained antibodies to Rauscher (R) cells but not to adult liver cells (L) or thymocytes (T) (R⁺L⁻T⁻ antibodies) were selected for further investigation and cloned. One such antibody was found to recognize a determinant found on erythroid precursors (see Results).

Assays for Reactivity of Monoclonal Antibodies

Enzyme-linked immunosorbent assay (ELISA). Rauscher cells, adult murine liver cells, or thymocytes were centrifuged for five

minutes at $700 \times g$ and fixed with 0.05% glutaraldehyde into 96 well flexible plastic round bottom wells (Dynatech, Alexandria, Va) at a concentration of 10^6 cells/mL (0.1 mL/well). The wells were washed twice and blocked with Dulbecco's phosphate-buffered saline (PBS), 1% bovine serum albumin (BSA; Miles Scientific, Naperville, Ill) for one hour. Supernatants from the hybridoma wells were added to each of the three test cell plates (Rauscher cells, liver cells, thymocytes) and incubated for 45 minutes at 4°C . The ELISA plates were washed with the PBS-BSA buffer and incubated with 50 μL /well of 1:1000 horseradish peroxidase-conjugated rabbit antirat IgG antibody (Cooper Biomedical, Malvern, Pa) for 45 minutes at 4°C . The plates were washed, and 50 μL of 6 mmol/L O-phenylenediamine/0.01% H_2O_2 (Sigma) substrate reagent was added to each well. The reaction was stopped by adding 2N HCl, and the resulting chromophore was measured at 490 nm with an EIA reader (Bio-Tek, Burlington, Vt).

Immunofluorescence. Antibody binding to Rauscher cells or to DBA/2J murine bone marrow cells, splenocytes, thymocytes, neutrophils, peritoneal macrophages, and platelets was assessed by fluorescence flow cytometry (FFC) with an Ortho Cytofluorograf System 50 interfaced with 2150 Ortho computer. Cells (5×10^6) were incubated with 100 μL of $\text{R}^+\text{L}^-\text{T}^-$ hybridoma supernatant for 30 minutes at 4°C . They were washed three times with PBS and then incubated with 100 μL of 1:25 fluorescein isothiocyanate-conjugated rabbit antirat IgG (Cooper Biomedical). The cells were washed and resuspended in 25 mmol/L HEPES-buffered MEM, 2% fetal calf serum, pH 7.3, for fluorescence analysis and sorting. Sorted cells were collected into 35 mm petri dishes containing 1 mL of heat-inactivated fetal calf serum. For subsequent morphologic examination, the cells were washed and resuspended in fetal calf serum, cytocentrifuged onto glass slides (Shandon-Southern Cytospin SCA-0030, Sewickley, PA) and stained with Wright's Giemsa (Harleco). For differential counts, at least 500 cells per slide were examined. Portions of cells were collected under sterile conditions for in vitro progenitor assays. Neutrophils were obtained from the peritoneal exudates of male mice three hours after a single injection of calcium caseinate.⁶ Microscopic examination of the cells fixed to glass slides and stained with Wright's stain confirmed that 80% to 90% of the cells were neutrophils. Peritoneal macrophages were harvested by peritoneal lavage of anesthetized but otherwise untreated mice.

In Vitro Hematopoietic Progenitor Assays

BFU-E, CFU-E, and CFC-E culture. The sorted cell populations were analyzed for BFU-E, CFU-E, and CFC-E⁷ in plasma clot culture.⁸ Bone marrow cells treated with antibody were separated by FFC into two populations, those exhibiting moderate-to-high fluorescence (positive) and those with low fluorescence (negative). Antibody-treated, unsorted cells served as the control for these experiments. CFU-E/CFC-E cultures were grown for 48 hours in the presence of 0.25 U erythropoietin/mL, while BFU-E cultures were grown for seven days in the presence of 3 U erythropoietin/mL (Connaught, Willowdale, Ontario). At specified times, the clots were transferred to microscope slides, fixed with glutaraldehyde, stained for hemoglobin with dimethoxybenzidine, and counterstained with hematoxylin. The slides were scored for both erythroid colonies from CFU-E (8 or more cells) and for erythroid clusters from CFC-E (3 to 7 cells).⁷ The seven-day cultures were scored for BFU-E-derived colonies consisting of three or more subcolonies.

CFU-C culture. The sorted populations were assayed for CFU-C granulocytic progenitor growth as described by Marchal and Milon.⁹ Bone marrow cells were plated in 96 well microtiter dishes at six concentrations, ranging from 400 cells to 12.5 cells/well (60 wells for each cell concentration), in DMEM containing 20% fetal calf

serum, 5×10^{-5} mol/L 2-mercaptoethanol in the presence of colony-stimulating factor (CSF) derived from both sera- and lung-conditioned media from endotoxin-treated mice.¹⁰ The cells were incubated for seven days in 10% CO_2 at 37°C . Cytocentrifuge preparations from the wells containing colonies demonstrated complete myeloid cell differentiation in this culture system, confirming the identity of the colonies as derived from CFU-C. Limiting dilution analysis permitted the determination of the number of precursor cells in the population. In this assay system diluting the concentration of cells plated increases the incidence of wells with no colonies. The percentage of wells lacking colonies for each cellular concentration plated was then plotted semilogarithmically. According to the Poisson distribution and assuming a random and independent distribution of progenitors throughout the wells, the concentration of cells plated in which 37% of the wells are negative for CFU-C colony growth is the cell concentration that contains one CFU-C.¹¹

Phenylhydrazine anemia. A phenylhydrazine-induced hemolytic anemia was generated in DBA/2J mice using a modification of the method of Spivak et al.¹² Mice were injected intraperitoneally with 0.04 mg phenylhydrazine (Sigma) per gram animal weight at 9 AM and 3 PM on day 1 and 9 AM on day 2. Blood was obtained on day 5 from the retro-orbital venous plexus.

Erythropoietin induction of Rauscher cells. Rauscher cells were induced with 2 U of erythropoietin/mL for specified time intervals ranging from five minutes to six days. Erythropoietin was prepared in our laboratory from the urine of anemic human donors and had a specific activity of 1050 U/mg. The cells were harvested, washed in PBS, and ERY-1 was measured by FFC. The changes in antigen density were quantitated by converting the median fluorescence intensity of the experimental samples from a log scale to linear fluorescence intensity units.^{13,14}

Western blot analysis of ERY-1 antigen. Whole cell lysates and plasma membrane preparations of logarithmically growing Rauscher cells were subjected to discontinuous polyacrylamide gel electrophoresis through 10% gels. The proteins were then transferred to nitrocellulose paper electrophoretically¹⁵ and remaining protein binding sites were blocked with a solution of 3% bovine serum albumin in 25 mmol/L Tris-HCl, 500 mmol/L NaCl, pH 7.5. The nitrocellulose was incubated for two hours with dilutions of ERY-1 monoclonal antibody (MAb) ascites (Deca-Probe, Hoefer Scientific, San Francisco), washed, and then incubated with 1:1000 horseradish peroxidase-conjugated goat antirat IgG. Bound antibody was detected with 4-chloro-1-naphthol and H_2O_2 .

RESULTS

Binding of Monoclonal Antibody ERY-1 to Rauscher Cells and to Normal Marrow Cells

Numerous supernatants from the fusion contained antibodies that bound to Rauscher cells but not to liver cells or thymocytes in the screening ELISA ($\text{R}^+\text{L}^-\text{T}^-$ antibodies; see Materials and Methods). The binding of these antibodies to Rauscher cells and to normal marrow cells was examined by FFC. The Rauscher cell-binding profile of one of these antibodies, designated ERY-1, is shown in Fig 1. Greater than 80% of Rauscher cells bound MAb ERY-1 compared to the control rat IgG. In contrast, only 26% of Friend murine erythroleukemia cells bound MAb ERY-1 (not shown), and this was at far lower fluorescence intensities than the Rauscher cells. Human K-562 cells did not bind MAb ERY-1.

The initial flow cytometric analysis of MAb ERY-1 binding showed that a population of cells within normal

Fig 1. Fluorescence flow cytometry profile of Rauscher cells analyzed with MAb ERY-1 (solid line). The dotted line represents normal rat IgG control.

murine bone marrow bound the antibody (Fig 2A). Those cells that exhibited MAb ERY-1 binding were a continuous rather than discrete population whose fluorescence distribution was a broad shoulder of gradually increasing fluorescence intensity when compared to the control cell population that was incubated with irrelevant rat IgG (Fig 2A). This fluorescence distribution was different from that obtained when an antimyeloid monoclonal antibody, MAb MYELO-2, was used (Fig 2B). In this case a discrete population of cells was well separated from the control (and nonreactive) population.

Using MAb ERY-1, we sorted normal bone marrow cells

Fig 2. Fluorescence flow cytometry profiles of bone marrow cells sorted with anti-Rauscher cell monoclonal antibodies ERY-1 (A) and MYELO-2 (B). The dotted lines are normal rat IgG controls.

Table 1. Binding of ERY-1 Monoclonal Antibody to Normal Murine Bone Marrow Cells Assessed by Fluorescence Flow Cytometry

Population	Cell Type (%)		
	Erythroid	Lymphoid	Myeloid
ERY-1 ⁺	44	17	39
ERY-1 ⁻	0	14	86
Unsorted	16	22	62

into "positive" (ERY-1⁺) and "negative" (ERY-1⁻) populations (see Fig 2A for sorting gates) and examined them morphologically after spinning onto glass slides, fixing, and staining (Table 1). The ERY-1⁺ population consisted of 44% erythroid cells, 17% lymphoid cells, and 39% myeloid cells. This was in contrast to the ERY-1⁻ population, which contained 0% erythroid cells, 14% lymphoid cells, and 86% myeloid cells. These data suggested to us that MAb ERY-1 recognized a determinant that was at least predominantly erythroid and prompted further investigation using highly enriched populations of hematopoietic cells.

Binding of Monoclonal Antibody ERY-1 to Enriched Populations of Hematopoietic Cells

Further confirmation of the erythroid nature of the ERY-1 antigen was sought by examining the binding of MAb ERY-1 to fetal and adult liver cells. Liver erythropoiesis is quite brisk in the 12- to 13-day-old murine fetus. However, it begins to decline markedly at day 14 and has essentially ceased at the time of birth. Using fluorescence flow cytometric analyses, we found that the 13-day murine fetal liver contained 70% ERY-1⁺ cells (Table 2). This value decreased to 35% ERY-1⁺ at day 14 and, finally, to a total absence of ERY-1⁺ cells in the adult. Thus, the pattern of MAb ERY-1 binding to murine fetal liver cells paralleled that of hepatic erythropoiesis, supporting the identification of the ERY-1 determinant as an erythroid antigen.

In contrast, MAb ERY-1 did not bind to enriched populations of neutrophils, splenic lymphocytes (predominantly B cells), thymocytes, peritoneal macrophages, or platelets (Table 2). These results provided strong evidence that the ERY-1 determinant is restricted to the erythroid lineage and that the presence of nonerythroid cells in the ERY-1⁺ population obtained after sorting normal bone marrow (Table 1) was due to the gate settings of the Cytofluorograf.

Table 2. Binding of ERY-1 Monoclonal Antibody to Murine Hematopoietic Cells

Cell Type	ERY-1 ⁺ Cells (%)

Platelets	<1

Identification of ERY-1⁺ Cells in the Bone Marrow, Spleen, and Peripheral Blood During Erythropoietic Stress

Our initial flow cytometric and morphological examination of MAb ERY-1 binding to normal bone marrow indicated that the monoclonal antibody bound to erythroid precursors. Therefore, conditions of erythropoietic stress that result in higher frequencies of erythroid precursors should cause an increase in the relative number of ERY-1⁺ cells. We compared the percentages of ERY-1⁺ cells present in the bone marrow, spleen, and peripheral blood of normal animals to those in animals with phenylhydrazine-induced hemolytic anemia (Table 3). The number of ERY-1⁺ cells in the normal bone marrow of three mice tested ranged from 12% to 19%. This value increased to 38% during phenylhydrazine anemia. Similarly, the number of ERY-1⁺ cells in the spleen rose from less than 1% in the normal spleen to 32% in the erythropoietic spleen of phenylhydrazine treated animals. Lastly, the peripheral blood of normal animals contained 0% ERY-1⁺ cells. This value rose markedly to 40% during phenylhydrazine anemia.

Binding of Monoclonal Antibody ERY-1 to Progenitor Cells

The data presented thus far indicated that the ERY-1 antigen is present on developing erythroid precursors but that it disappears sometime before erythroid maturation is complete. Since this pattern implied that the expression of ERY-1 is specific for certain states of erythroid differentiation, we considered it important to determine the distribution of this determinant among various progenitor cells. The analysis was performed as follows. Normal bone marrow cells were reacted with ERY-1 monoclonal antibody and separated into ERY-1⁺ and ERY-1⁻ populations by FFC. Approximately 15% to 20% of the normal cells were designated ERY-1⁺. Sorted populations of cells that were either ERY-1⁻ or moderately to strongly ERY-1⁺ were collected and assayed *in vitro* for BFU-E, CFU-E, and CFC-E, and for granulocyte progenitors (CFU-C) (Table 4).

The most primitive of the erythroid progenitors, BFU-E, was completely absent from the ERY-1⁺ population and was present in the ERY-1⁻ population. This was in marked contrast to the more mature progenitor CFU-E which was found almost exclusively (98%) in the ERY-1⁺ population. This appearance of the ERY-1 antigen on the CFU-E was

maintained into the most mature progenitor population, the CFC-E, all of which were ERY-1⁺. As expected, the granulocyte progenitors, CFU-C, were found highly concentrated in the ERY-1⁻ population. Thus, detectable ERY-1 expression appears to begin between the BFU-E and CFU-E stages of erythroid progenitor differentiation and continues through erythroid progenitor development. The determinant is found on identifiable precursors but disappears before final erythrocyte development (Fig 3).

ERY-1 Expression During Rauscher Cell Differentiation

The pattern of ERY-1 antigen expression occurring during normal erythroid development was reflected during the differentiation of Rauscher cells. As shown in Fig 4, the density of ERY-1 antigen was slightly higher after six hours and doubled within the first day of erythropoietin induction, analogous to the increase found as BFU-E develop into CFU-E. This was followed by a reduction to 137% of the starting density after two days and a dramatic decrease to less than 7% of maximum after six days of induction with erythropoietin. This pattern of ERY-1 expression, which was identified in three replicate experiments, strongly resembles the pattern found during normal erythropoiesis, further confirming the similarity of Rauscher cell differentiation to normal bone marrow erythroid development. In similar experiments using dimethyl sulfoxide induction, no initial increase in ERY-1 was detected. As DMSO induction was continued, however, ERY-1 expression diminished correspondingly and was less than 10% after six days.

Western Blot Analysis of ERY-1

Rauscher cell plasma membrane preparations and whole cell lysates were subjected to SDS gel electrophoresis and Western blot analysis in an effort to begin a biochemical characterization of the ERY-1 antigenic determinant. However, despite repeated efforts, no specific binding of the MAb to any protein bands was found. This strongly suggests that the epitope identified by the antibody on the native antigen is altered upon denaturation with SDS.

Fig 3. Model of ERY-1 antigen expression during normal erythropoiesis.

Fig 4. Effect of erythropoietin induction on Rauscher cell ERY-1 membrane antigen density. Units of antigen density are linear fluorescence units as volts converted from the log scale.^{13,14} The fluorescence obtained using equivalent concentrations of irrelevant rat IgG was less than 0.05 units at all time points and has been subtracted from the ERY-1 values. The points represent the mean $\pm$ SE of three replicate experiments.

DISCUSSION

In the present study we have employed the continuous cell line Rauscher murine erythroleukemia as immunogen and have generated a monoclonal antibody that recognizes an antigenic determinant, designated ERY-1, present on normal erythroid progenitors and precursors. The data indicate that the ERY-1 antigen is restricted to the erythroid lineage and is expressed only during certain stages of erythropoiesis.

Initial FFC analyses (Fig 2A) showed that the population of bone marrow cells expressing ERY-1 was continuous with the negative population rather than separated discretely (Fig 2B). Hence, the fluorescence intensities employed to discriminate "positive" from "negative" cells were necessarily somewhat arbitrary. The consequences of this partial overlap of populations is seen in Table 1. Thus, although no erythroid precursors were found in the ERY-1⁻ population (ie, all erythroid precursors were ERY-1⁺), the ERY-1⁺ population in this analysis was not exclusively erythroid. Although an alternate explanation for this observation is that a portion of both myeloid and lymphoid cells actually expresses the ERY-1 determinant, this seems quite unlikely, since the ERY-1 determinant was not found on highly enriched populations of these and other nonerythroid hematopoietic cells (Table 2).

ERY-1 antigen was not found on the early erythroid

progenitor, BFU-E. In this regard it is important to note that the lower limit of detection of cell surface determinants using conventional FFC, such as that employed in this study, is approximately 10,000 molecules per cell. Thus, the designation of BFU-E as ERY-1⁻ must be considered as relative rather than absolute. Nonetheless, ERY-1 expression is clearly increased markedly in the CFU-E and CFC-E and decreases thereafter during precursor maturation. Importantly, this pattern of ERY-1 expression was exhibited with remarkable fidelity during erythropoietin-induced Rauscher cell differentiation, supporting the use of these cells as a model system for the study of erythropoiesis.

Monoclonal antibodies that recognize surface determinants restricted to immature mammalian erythroid cells have been reported previously. Yokochi et al described two antibodies that bind to immature human erythroid cells at different stages of differentiation.¹⁶ A third MAb, reported recently from this same laboratory, binds to CFU-E, erythroblasts, and mature erythrocytes.¹⁷ Tonevitsky et al have developed a rat MAb that recognizes a 69 kD antigen found on murine nucleated red cells and reticulocytes.¹⁸ Although many other MAbs that bind to erythroid cells have been described, strict lineage specificity is quite unusual.

At present, the identity and function of the ERY-1 antigen is unknown. It does not appear to be associated with the transferrin receptor since it exists at a very low density on Friend cells which are known to express greater than 10⁵ copies of the transferrin receptor per cell.¹⁹ Moreover, the absence or presence of excess transferrin has no effect on the binding of MAb ERY-1 to Rauscher cells (data not shown). Since the pattern of ERY-1 expression during differentiation of erythroid progenitors resembles the pattern of erythropoietin sensitivity, it is possible that the ERY-1 antibody recognizes the erythropoietin receptor or a macromolecule associated with it. The addition of ERY-1 antibody to Rauscher cell cultures results in striking cell clustering but does not interfere with the ability of the cells to grow or to respond to erythropoietin (data not shown). Nevertheless, the antibody could recognize a portion of the receptor remote from the hormone-binding domain. Another possibility to be considered is a relationship between the ERY-1 determinant and the fibronectin binding sites found on erythroleukemia cells and on immature, normal erythroid cells.^{20,21} ERY-1 expression during normal and Rauscher cell erythropoiesis is remarkably similar to that reported for these sites. Finally, the similarity of ERY-1 to EP-1, a determinant found on human erythroid cells,¹⁶ must be noted. Establishing the identity and function of ERY-1 and other related differentiation-specific antigens may be pivotal in elucidating the processes of erythropoietic commitment and differentiation.

Hydroxyurea-Induced Augmentation of Fetal Hemoglobin Production in Patients With Sick Cell Anemia

By Samuel Charache, George J. Dover, Martha A. Moyer, and Jay W. Moore

Five patients with sickle cell anemia were treated with hydroxyurea (HU), in hopes of augmenting their production of fetal hemoglobin. Laboratory responses in two patients treated for more than 2 years were encouraging and there were suggestions of clinical improvement. Long-term HU therapy should be considered for severely affected adults with sickle cell anemia who are willing to accept what is probably a small risk of carcinogenesis. Preliminary chromosomal analysis and knowledge of the clastogenic prop-

erties of HU suggest that conception and pregnancy should be avoided. Pharmacokinetic studies will probably be necessary to adjust individual dosage schedules so that cytotoxicity is avoided. F cell responses can be seen in 2 to 3 weeks if the HU dose is optimal, but establishment of a large number of F cells in the circulation may take a month or longer.

© 1987 by Grune & Stratton, Inc.

IN 1948 Janet Watson reported that the red cells of newborns with sickle cell anemia did not sickle and suggested that inhibition of sickling was due to the presence of fetal hemoglobin (Hb F).¹ Discovery of pancellular hereditary persistence of fetal hemoglobin (HPFH) and its interaction with sickle cell trait (S/HPFH) provided clinical evidence for inhibition of sickling by Hb F,² and the studies of the Singers,³ Bertles et al,⁴ Nagel et al,⁵ and Goldberg et al⁶ provided explanations for inhibition at a molecular level.

In patients, it has been difficult to demonstrate a beneficial effect of increased Hb F levels on severity of illness, in no small part because of difficulties in defining severity. Increased longevity^{7,8} in adults, decreased sequestration crises in children,⁹ and decreases in certain well-defined events¹⁰ have been associated with increased Hb F, as have the milder courses of Saudi Arabians with the disease.^{11,12}

Much effort was devoted to attempts at therapeutic exploitation of these findings,¹³ but it was not until DeSimone et al showed that administration of 5-azacytidine (AzaC) to anemic baboons caused remarkable increases in Hb F production¹⁴ that clinical studies became possible. Cast in contemporary terms, but based on much older work,¹⁵⁻¹⁷ the goals of such studies were to raise the proportion of Hb F-containing cells (F cells) and the amount of Hb F/F cells, and compare these increases with decreases in hemolysis and the severity or frequency of vaso-occlusive crises.

We¹⁸ and others¹⁹ showed that AzaC increased Hb F levels in humans, and we gave preliminary evidence that it might have therapeutic benefit when used on a long-term basis. Methods were developed to permit its oral administration, a necessary prerequisite if it was to be used on a long-term basis,²⁰ but enthusiasm for use of AzaC was chilled by early^{21,22} and more recent²³ reports that the drug was probably a carcinogen in laboratory animals.

The mechanism of action of AzaC on Hb F synthesis is unclear.^{24,25} Three hypotheses have been advanced: (1) derepression due to hypomethylation of cytosine residues,^{18,19} (2) "recruitment" of early red cell precursors during recovery from drug-induced marrow suppression,²⁶ and (3) direct "reprogramming" of relatively late precursors by a direct effect of the drug.²⁷ The debate is still in progress, but the recruitment hypothesis led to use of hydroxyurea (HU) for augmentation of Hb F synthesis.²⁸⁻³¹ HU is readily available and easily administered; although reported to be noncarcinogenic³² in a limited study, it is a mutagen³³ and teratogen.^{34,35}

We report here our experience at The Johns Hopkins Hospital with long-term use of HU for treatment of patients with sickle cell anemia. Questions discussed include dosage regimens, hematologic effects, clinical responses, and untoward effects of the drug. Intensive observation of two patients for more than 2 years permits speculation on the number of F cells and proportion of Hb F needed to ameliorate crises and the role of dense red cells in crises, and has led to suggestions for future trials of the drug.

MATERIALS AND METHODS

Patients were considered for admission to the study only if they had failed or could not continue any other means of therapy and were seriously disabled by their disease. They were informed of potential carcinogenesis, and consent was not obtained until both the patient and a friend or relative had attended several sessions at which potential risks and benefits of treatment and obligations of investigator and research subject were described in detail. The consent form and the process of obtaining consent were approved by The Johns Hopkins Committee on Clinical Investigation.

Capsules of HU (Hydrea, Squibb, Princeton, NJ) were purchased at a pharmacy; no attempt was made to "blind" either patient or investigator. Baseline studies and initiation of therapy were done in the Inpatient Research Center; thereafter, patients were followed at 1- to 4-week intervals in the Outpatient Research Center. Patient H was followed up by Drs. P. Roberts and P. Milner (Medical College of Georgia, Augusta), and samples were sent by overnight express mail.

Blood counts were done by a Coulter S+IV (Coulter Electronics, Hialeah, FL), reticulocytes were counted using thioflavin T and an EPICS-C flow cytometer (Coulter Electronics),³⁵ and Hb F in hemolysates was measured by alkali denaturation. Proportion of F cells (red cells that contain Hb F) and F reticulocytes (reticulocytes that contain Hb F) were assayed by previously described methods³⁶; the amount of Hb F/F cell was calculated from the Coulter mean corpuscular hemoglobin (MCH), the hemolysate Hb F level, and the proportion of F cells (Table 1); the calculation was validated by independent immunoprecipitation reactions in some instances.³⁷ Because MCH is the same in F and non-F cells,³⁸ Hb S/F cell and S/S cell were readily calculated. The proportion of dense red cells ($d > 1.120$, mean corpuscular hemoglobin concentration [MCHC] > 37 g/dL) and median corpuscular hemoglobin concentration were estimated after centrifugation through mixtures of phthalate esters of varying density.³⁹ Blood HU levels were measured at intervals after a test dose of 25 mg/kg (to the nearest 500 mg), using the method of Fabricius and Rajewsky⁴⁰ as modified by Belt et al.⁴¹ DNA haplotypes associated with the γ - δ - β gene cluster were determined in the laboratory of Dr S. Antonarakis (Johns Hopkins University School of Medicine, Baltimore).⁴² For chromosomal analysis, lymphocytes from peripheral blood were stimulated to divide with phytohemagglutinin and cultured for 72 hours in Eagle's minimum essential medium supplemented with 13% fetal calf serum (GIBCO, Grand Island, NY). Cells were arrested in metaphase with demecolcine, and a minimum of 30 G-banded chromosomes were counted and analyzed (without knowledge of the patient's identity) for structural rearrangements and aberrations.⁴³

When patients developed pain, they were treated at home with oxycodone and acetaminophen capsules; if pain could not be managed, they came to the emergency department. A decision whether or not they required admission was made within 12 hours by the staff there, with no advice or input from the investigators; decisions regarding discharge were made by the patient. Patients often asked about their hemoglobin or hematocrit levels but were not aware of Hb F, F reticulocyte, or F cell values. All patients were told to take 1 mg folic acid per day.

Patients

Responses of patients A and C to AzaC were described earlier¹⁸ and their and patient E's initial responses to HU have also been described.³¹ Patient A is now 33 years old and has transfusion-related hemochromatosis and diffuse but asymptomatic bone disease. Patient C is now 47; he has severe bone disease and early renal disease and has suffered two strokes. Patient E is a 31-year-old woman who has consumed large amounts of narcotics because of recurrent intractable abdominal pain; she was referred by Dr T.

Gabuzda (Philadelphia). Patient F is a 25-year-old woman who had unremitting ankle ulcers and severe anemia; she could not be transfused because of prior alloimmunization. Patient G, 31 years old, was referred by Dr S. Glaser (Baltimore) because of recurrent severe pain; she had had a delayed transfusion reaction after exchange transfusion and did not wish to be transfused again. Patient H, a 35-year-old man, could not be transfused and had shown no improvement when treated with DDAVP, heparin, or phlebotomies; his mean corpuscular volume (MCV) on admission was 62 but rose to normal after treatment with iron. When his Hickman catheter became infected and had to be removed, he withdrew from the study. None of the patients was physically dependent on narcotics.

RESULTS

Drug Dosage

Drug regimens used and some measures of red cell production and Fb F synthesis are summarized in Table 2. Patients A and C were initially treated with 50 mg/kg 3 days a week, and both became reticulocytopenic³¹; treatment was resumed at lower dosage after recovery from marrow depression, but the HU dosage did not become stable until day 98 for patient A and day 50 for patient C. In patients E and H, F reticulocyte production stabilized after about 3 weeks (Fig 1) and the tabulated data start at that point. Patient G, not shown in Table 2, received only two doses of HU for measurement of its renal clearance and then withdrew from the study. Patient H, followed with some difficulty because of lack of venous access and residence in Georgia, was treated conservatively.

Our earlier studies³¹ indicated that marrow suppression might be related to decreased renal clearance of HU in patients whose kidneys did not function normally.⁴⁴ Serum urea nitrogen and creatinine, creatinine clearance, and HU clearance were measured in each of six patients (Table 1). As previously reported,³¹ the clearance of HU in sickle cell anemia (SS) patients given a standard dose of HU (25 mg/kg) varies considerably. We noted (Table 1) that the F reticulocyte response ratio (absolute F reticulocyte count on day 8 after the clearance study divided by the count before therapy) was inversely correlated with peak and 6-hour HU plasma concentrations, as well as the rapidity of plasma HU clearance as measured by total area under the concentration-time curve (AUC).⁴⁵

F cell characteristics were calculated as follows: MCH in S Cells = MCH in F Cells; F/F Cell = [(MCH) (%F)/% F Cell]; S/F Cell = MCH - F/F Cell; S/S Cell = MCH; MCSHC in F Cells = (S/F Cell/MCV).

*Before AzaC; transfused.

†Two weeks after end of AzaC therapy.

‡Transfused.

§Coulter counter; other values are based on density gradient centrifugation.

Hematologic Effects

The proportion of F reticulocytes, F cells, and Hb F in hemolysates rose during therapy with HU (Table 2). Indices of Hb F production varied considerably over time but appeared to behave in a more concerted fashion in patient A than in patient C. Patient A has shown an increase in Hb F

Fig 1. Response of patients E and H to HU. E had been transfused, and H was iron deficient before therapy. Black bars represent HU and the stippled bar FeSO₄ treatment.

production in recent months, coincident with a change in treatment from three to four days per week. The change has been gradual, over a period of 5 months. Patient E reached maximum F cell and Hb F levels after about 2 months of treatment; patient H, treated more conservatively, showed increasing levels when therapy was stopped after 3½ months (Fig 1). Absolute reticulocyte counts fell below baseline at some points in most patients but remained over 200,000/mm³ (except during folate deficiency in patient A). No patients developed thrombocytopenia or severe neutropenia (<2,000/mm³), but patient C exhibited intermittent lymphocytosis (see below under Clinical Responses). There was no clear relationship between DNA polymorphisms within the γ - δ - β gene cluster^{42,46,47} and F cell response.

MCV and MCH rose markedly in patients who responded (Table 2), but there was little or no change in median MCHC as estimated from phthalate ester density gradients. As expected,⁴⁸ the calculated Hb F/F cell and number of F cells varied independently, and the concentration of Hb S within F cells decreased. The early rise in Hb F (and MCV) observed in patient H may have been related to treatment of iron deficiency (Fig 1).^{49,50}

Clinical Responses

Patient A's crises have become shorter and milder (Fig 2) but still persist. Patient C has occasional attacks of a few hours' duration but has resumed full-time employment.

Fig 2. Clinical responses to HU therapy. Days of observation are shown in parentheses, and percentages of those days spent in hospital because of vaso-occlusive crises are plotted.

Patient E continued to complain of intermittent abdominal pain during treatment; a biliary stricture was discovered, and reconstructive surgery was done. Her complaints disappeared, and she elected to discontinue therapy. Patient F showed no healing of her ankle ulcer and only a small response to HU therapy. The crisis she experienced while hospitalized was quite mild but represented a change from her usual condition. Patient H is still incapacitated by his disease but did not receive enough HU to be considered a treatment failure.

An attempt was made to relate the occurrence of inpatient crises in patients A and C to one or more of the measurements made on red cells. There was little difference between sets of data collected during vaso-occlusive crises, between crises, and during the week preceding a crisis (while the patient was pain free). In particular, there were no differences in red cell distribution width (RDW) or the proportion of dense cells between the three clinical situations. It should be noted that patient C had almost as many crises as patient A, but they lasted for one to two days, rather than for weeks at a time.

Untoward Effects

Toxicity. Patient A developed megaloblastic anemia on day 416, which responded promptly to folic acid; he had run out of tablets several months before. On day 576 he was admitted with atrial fibrillation, which responded to a brief course of digoxin and has not recurred; the etiology was thought to be cardiac hemochromatosis. An area of altered density in his liver on abdominal sonography could not be detected by computed tomography (CT) scan and was thought probably to be due to fibrosis.

Patient C, who has intermittent lymphocytosis, developed disseminated herpes zoster on day 335. Response to acyclovir was prompt; his varicella zoster antibody titer was 1:200 and rose to >1:2,000; he was not anergic; proportions of T and B

cells were 60% and 30%; and his T4-T8 ratio was 1:1. At the beginning of AzaC therapy his differential white count was normal, but he had too few T cells to count; the T4-T8 ratio was 0.5 when he was switched to treatment with HU. It is currently 0.6 and that of patient A is 1.2.

Patients F and H complained of mild nausea after taking several capsules of HU simultaneously, but these complaints diminished when the dose was divided or lowered. Patient G developed a high fever after one HU clearance study but did not after a second; her participation in the study was terminated by mutual agreement.

Chromosomal analyses. During therapy with AzaC patients A and C were found to have an increased number of chromosomal structural rearrangements or deletions; unfortunately, chromosomal studies were not carried out before AzaC therapy. Specimens from patients E, G, and H yielded abnormal patterns before treatment with HU. Subsequent analyses during HU therapy (Fig 3) showed no progression of changes in patients A, C, or H. Many affected cells in patient G had more than one of the acquired aberration, suggestive of a recent viral infection.⁵¹ She also was the only patient transfused within several weeks of chromosomal analysis. Potential causes of the observed rearrangement and breaks included an effect of prior transfusion, narcotics, street drugs, unrecognized viral infection, or a complication of the therapeutic regimen.⁵²

Fig 3. (A) Chromosomal abnormalities in patients treated with HU (A through H) and in untreated SS controls studied at the same time (1 through 7). Subscripts a through c represent serial samples: At least 30 cells were examined in each analysis (mean = 61). (B) Solid bars represent numbers of breaks observed, and open bars represent numbers of affected cells. The control patients were 6 to 34 years of age (mean = 24); five of them had been extensively transfused, but only patient 1 had received significant amounts of narcotics. INVER = inversion; DELET = deletion; TRANS = translocation.

Two groups of controls were studied at the same time as the patients who were treated with HU. Seven sickle cell anemia patients, most of whom had been extensively transfused but had little exposure to narcotics, served as untreated controls and were studied at the same time as the treated patients. One SS control had a single chromosomal rearrangement as did two of 13 AA controls. One SS control had a number of chromosomal aberrations, but as noted in the specimen from patient G, there was more than one aberration per affected metaphase (17 aberrations/9 affected metaphases), which is compatible with a recent viral infection.⁵¹

No structural rearrangement or deletion was found in more than one cell, and the chromosomal breaks were random. Abnormalities were found in two of 13 normal (AA) controls, but three cells were involved in each of them.

Carcinogenesis. No patient has developed evidence of a malignant disorder on physical examination. Chest x-rays, bone surveys, abdominopelvic CT scans, and sonograms of the testicles have been done in patients A and C at 6-month intervals; neither they nor physical examinations have disclosed any new abnormalities since the beginning of experimental therapy with AzaC (44 months in patient A and 35 months in patient C).

DISCUSSION

Prediction of Response

We have recognized three of the factors that appear to determine the response of SS patients to HU: HU clearances, baseline F reticulocyte production, and dosage regimen.

Earlier we observed that F reticulocyte production after HU administration was related inversely to the serum creatinine level and directly to the rapidity of HU clearance from plasma.³¹ Those suggestions are supported by the data reported here. In the previous report, three patients with serum creatinine above 1.0 mg/dL showed marrow suppression and failure to increase their F reticulocyte levels. No patient in this report has a creatinine level above 0.9, and all responded with substantial increases in F cell production. In the earlier report, rapid HU clearance appeared to be associated with a high F reticulocyte response. Here studies of HU clearance (including AUC analyses as well as plasma levels) could be used to predict initial and highest mean F reticulocyte response ratios. They could not be used to predict highest mean F cells, Hb F, or F/F cell, nor did they predict the mean F reticulocyte count for a given dose of HU per se. For example, the patients with the fastest (A) and slowest (E) clearances had the highest and lowest F reticulocyte response ratios, but the maximum mean F cell and Hb F levels they achieved were similar (Tables 1 and 2).

A second factor involved in determining the response to HU is the patient's genetically determined baseline F reticulocyte production level.^{53,54} This level ranges from 4% to 50% F reticulocytes,^{48,53} is inherited,⁵⁴ and is fixed some time after the first year of life.⁵⁵ As we suggested earlier, the patients with high initial counts (C and E) eventually achieved the highest mean F reticulocyte counts during treatment, and C achieved the highest F cell count, Hb F level, and Hb F/F

cell (Table 2). DeSimone obtained similar results in baboons treated with AzaC, in a situation where inherited variations of F cell production are similar to those in humans.²⁴ DNA polymorphisms around the γ - δ - β gene cluster have been reported to correlate with increased levels of Hb F,^{46,47,56} but such analyses in our patients did not yield a convincing Hb F pattern.

A third determinant of the F reticulocyte response is dosage regimen. The two patients studied for several years appear to have different optimal regimens. During recent months patient A responded better to HU when it was given four days a week rather than three, and Alter and Gilbert have reported that patients receiving HU for myeloproliferative syndromes produce more Hb F on a daily rather than an intermittent dosage schedule.⁵⁷ Our present hypothesis is that patients' ability to rapidly excrete HU and their baseline F reticulocyte production levels are important determinants of their response to HU, but that the influence of the former, at least, can be modified by manipulation of dosage regimens. Individuals with low baseline F reticulocyte levels and delayed HU clearance will be the least likely to respond to therapy, and vice versa. Patients who fall between these extremes can be expected to show some response, but the magnitude of that response is as yet undetermined.

Hematologic Effects

The best dosage regimen should be one that maximally increases both the number of F cells and the amount of Hb F within those cells. To assess production of F cells, we have measured absolute numbers of F reticulocytes, which reflect changes in erythropoiesis as well as Hb F synthesis. Uncertainties about relations between dosage regimen and response have prompted us to continue direct measurements of F cell production. Macrocytosis was a constant result of treatment, damped in patient H by iron deficiency and coexisting α -thalassemia (α -/ α); PF Milner, personal communication, December 1985). As was observed with AzaC, MCH rose proportionately, the increase reflecting an increase in the amount of Hb S/per cell as well as Hb F in the F cells. We have previously reported that the proportion of dense cells (MCHC > 37 g/dL) did not decrease when patients A and C were treated with AzaC.²⁰ Here we show that the proportion of such cells did not decrease during HU therapy (Table 2), nor did it change in relation to crises.

The intraerythrocytic concentration of Hb S, a prime determinant of sickling tendency,⁵⁸ fell in F cells. In patient C the mean corpuscular sickle hemoglobin concentration (MCSHC) (Table 2) fell from about 32 to 22 g/dL in F cells. This fall in MCSHC would prolong the delay time (tenth time)^{59,60} of his F cells from 30 minutes to three to four minutes, or decrease their polymer fraction at 70% oxygen saturation⁵⁸ from 0.12 to 0.

Clinical Responses

In patients A and C, who did not know their F cell or Hb F levels, there was a relation between admissions for painful crises and symptom-free periods and their F cell production, strongly suggesting that the improvement we observed was not a placebo effect. Crises were less severe and less frequent

when Hb F was 8% to 10% and there were 55% to 60% F cells; they were virtually eliminated when Hb F was 15% to 18% and there were 60% to 70% F cells. The latter levels are lower than the >20% Hb F reported by Powars et al⁶¹ to be associated with fewer painful events and lower than the mean value of 25% found in mildly affected Saudi Arabian SS patients.^{11,12} On the other hand, patient E epitomizes the hazard of interpreting subjective complaints: she did not improve clinically despite a substantial increase in Hb F synthesis and then improved so rapidly after biliary tract reconstruction that she considered HU therapy unnecessary.

Untoward Effects

Toxicity. Atrial fibrillation in patient A was more likely related to hemochromatosis than to HU therapy. Development of mild but disseminated herpes zoster in patient C may have been related to HU therapy, but the patient's excellent clinical response to HU has encouraged him (and us) to continue treatment. Abnormal numbers of lymphocytes and striking abnormalities among his T cells may be related to prior transfusions^{62,63}; these changes have not progressed during treatment, nor have similar but less marked changes in patient A. Bone marrow depression has not been a problem with the doses we used, after the effect of subclinical renal disease was appreciated.

Chromosomal analyses. Discovery of chromosomal breaks and rearrangements during AzaC therapy in patients A and C prompted us to carry out chromosomal analyses in all other patients, as well as in untreated SS patients and normal controls. Some patients who have not received any cytotoxic drug have chromosomal abnormalities (Fig 3), and serial studies of patients A, C, and H showed that such

abnormalities have not progressed during treatment. Hydroxyurea is reported to be a strong inducer of chromosomal breaks (a "clastogen") in vitro but to have weak activity in inducing sister-chromatid exchanges.⁶⁴ Lymphocytes from patients with psoriasis treated with HU yielded abnormal karyotypes, but no control studies in untreated psoriatics were performed.⁶⁵ Cytogenetic aberrations do occur in normal volunteers⁶⁶; our data must be interpreted cautiously because our patients have been exposed to a variety of substances and treatments in addition to HU. Studies of patients and normal controls support such an interpretation, but it would seem prudent that patients receiving HU avoid conception or pregnancy.

Carcinogenesis. The risk of carcinogenesis in humans from HU is unknown. The drug is teratogenic and mutagenic^{33,34} in laboratory animals, but aspirin was equally teratogenic in a recent study.⁶⁷ HU induces sperm abnormalities in mice⁶⁸ but suppresses two-stage carcinogenesis in mouse skin^{69,70} and was considered noncarcinogenic in two small studies in animals.^{32,71} The best clinical evidence is inconclusive: patients with polycythemia vera who have been treated with HU show insignificant differences in the incidence of neoplasms when compared with patients treated only by phlebotomy.⁷² The series is not large (53 patients), and observations have continued for a median of only 5 years, but we have interpreted these data to our patients as indicating "safety unproved, but risk probably small."

ACKNOWLEDGMENT

Chromosomal analyses were done in the laboratory of Dr George H. Thomas; his advice and encouragement are gratefully acknowledged. Dr Constance T. Noguchi provided helpful advice, and Dr Stylianos E. Antonarakis analyzed haplotypes.

Lithium Augments GM-CSA Generation in Canine Cyclic Hematopoiesis

By William P. Hammond, Elin R. Rodger, and David C. Dale

Cyclic hematopoiesis in gray collie dogs can be cured by lithium treatment. We examined the mechanism of lithium's effect by developing an assay for the canine equivalent of GM-CSF (called GM-CSA). Phytohemagglutinin (PHA)-stimulated canine blood mononuclear cells produce GM-CSA in a dose-dependent manner; this GM-CSA stimulates more neutrophil-containing colonies than does endotoxin-treated dog serum. Production of GM-CSA by PHA-stimulated normal dog cells was not altered by lithium.

STUDIES OF CYCLIC HEMATOPOIESIS in gray collie dogs have shown that the regular 12-day periodicity of cell count fluctuations is due to changing marrow production rates and can be transferred or cured by bone marrow transplantation.¹⁻⁶ We and others have shown that the numbers of committed erythroid and granulocytic progenitor cells fluctuate over the cycle period and do so out of phase from their differentiated progeny.⁷⁻¹⁰ In studies of the effects of endotoxin and lithium treatment on these dogs, we showed that treatment abrogated the cyclic fluctuations of the progenitors as well as the blood cell counts.^{7,10-12} We also showed no differences in serum colony-stimulating activity (CSA) levels, responsiveness to CSA, or tritiated thymidine suicide rates of the granulocyte-macrophage progenitor cells (CFU-c) over the period of the cycle and were unable to show that successful treatment induced any change in these variables.^{7,12}

Because the assay system we had used to measure CSA produced colonies from the CFU-c that were primarily macrophagic (with a minor population of neutrophilic progenitor cells), we considered the possibility that an alternative source of CSA containing a canine equivalent of GM-CSF would be a more useful probe into the genetically aberrant regulatory system. Phytohemagglutinin (PHA)-stimulated blood mononuclear cells have been shown to elaborate GM-CSF in human and murine systems and served as the model system for these studies.¹³⁻¹⁶ We have now demonstrated a canine equivalent of GM-CSF (which we here call GM-CSA), have examined its elaboration by normal and gray collie dog mononuclear cells, and have measured lithium's effect on its generation.

MATERIALS AND METHODS

Dogs. Male and female gray collie dogs from 2 to 60 months of age and weighing from 5 to 25 kg were housed in individual cages or runs as previously described.^{7,10-12} Normal mongrel dogs and normal littermates of the gray collies served as controls. Blood specimens were routinely drawn from the cephalic vein of unanesthetized dogs; blood lithium levels were drawn before that day's dose when indicated. Dogs treated with lithium were given lithium carbonate capsules, 300 mg daily, and dosages were adjusted to keep serum lithium levels between 0.5 and 1.4 mEq/L as previously described.^{11,12}

Blood counts and bone marrow aspirates. Blood counts were performed by standard methods. For marrow aspirates the dogs were anesthetized with intravenous thiamylal sodium (Bio-tal; Bio-Ceutic Laboratories, St Joseph, MO), 15 to 20 mg/kg. Bone marrow was obtained from the humerus, femur, or iliac crest, heparinized, and diluted in 5 mL tissue culture medium.

However, cells from gray collies during their neutrophilic period increased their GM-CSA when lithium (2 mEq/L) was added to low doses of PHA, whereas neutropenic gray collie cells did not. These data suggest that lithium could modulate cyclic hematopoiesis by increasing intramedullary GM-CSA at the time when marrow neutrophilic progenitor cells are at their nadir.

In vitro bone marrow culture. Granulocyte-macrophage progenitor cells were grown as previously described.^{7,12} Final plating suspensions contained 1 to 2×10^5 nucleated cells per milliliter, 10% fetal calf serum, 0.3% agar, and a source of CSA. All assays were run in triplicate. Incubations were carried out for variable numbers of days, as indicated in Results. Colonies of 50 or more cells were counted with an inverted microscope and results expressed as colonies per plate or 10^5 nucleated marrow cells (total CFU-c) or as a percentage of control colony growth. Colony subtypes were identified as neutrophil, macrophage, or mixed colonies as described previously.¹²

Colony-stimulating activity. The standard CSA used in our earlier studies was postendotoxin dog serum (PEDS).^{7,12} Such serum is maximally active when added at 5% to 10% vol/vol in dog marrow cultures and was used as the control CSA source in the current studies.

PHA-stimulated leukocyte conditioned medium (PHA-LCM) was prepared in a manner similar to that used for human and murine cells.¹³⁻¹⁵ Dog peripheral blood was heparinized (beef lung heparin; Upjohn Co, Kalamazoo, MI, 20 U/mL), diluted 1:1 in Hanks' buffered saline solution (BSS; GIBCO, Grand Island, NY) and layered over Ficoll-Hypaque solution (density 1.074 to 1.076, osmolality 295 to 300). After spinning at 400 g for 35 minutes at 4 °C, the mononuclear cells were removed from the interface zone, washed three times, resuspended in fresh medium, and counted. Differential count of mononuclear cells from neutropenic gray collies revealed fewer than 0.2% neutrophils, $47\% \pm 5\%$ lymphocytes, and $44\% \pm 5\%$ monocytes. Both normal dogs' and neutrophilic gray collies' mononuclear cell populations contained more neutrophils (from 7% to 15%, $P < .01$) and fewer monocytes (from 20% to 28%, $P < .05$) than neutropenic gray collies but had similar numbers of lymphocytes ($P > .10$). Differential counts of neutrophils, monocytes, and lymphocytes were not statistically significantly different between normals and neutrophilic gray collies ($P > .08$). The cells were placed in plastic tissue culture flasks (T-75; Falcon, Cockeysville, MD) containing supplemented tissue culture medium, 20% fetal calf serum (GIBCO), PHA (M form) (GIBCO) at final dilutions of 1 to 50 μ g/mL, and in some flasks, lithium chloride at 2×10^{-3} mol/L. These flasks were incubated at 38 °C, in 5% CO₂ for seven days. The supernatants were then removed, centrifuged twice at 1,000 g for 15

minutes to remove cellular debris, and stored at -10°C until assayed for CSA. PHA-LCMs were assayed at 10% vol/vol with 5% normal dog serum to compare with 5% PEDS.

Modulation of CSA. Modulation of CSA in these PHA-LCMs was tested in two ways. To determine whether LiCl modulated CSA generation by mononuclear cells independent of T lymphocytes, some flasks were prepared with addition of the potent T lymphocyte inhibitor cyclosporine at $3\text{ }\mu\text{g/mL}$ (kindly provided by Dr Joachim Deeg, Fred Hutchinson Cancer Research Center, Seattle). In addition, to eliminate the contribution of carryover of lithium in PHA-LCMs prepared with LiCl, we dialyzed two sets of conditioned media against three changes of Hanks' BSS with $100 \times$ volume excess at 4°C . Dialyzed conditioned media were then compared with each other and to nondialyzed aliquots of the original PHA-LCM.

Tritiated thymidine ($^3\text{H-TdR}$) suicide and velocity sedimentation studies. We estimated cell cycle status of CFU-c by $^3\text{H-TdR}$ suicide as previously described.⁷ The percentage of thymidine suicide was calculated by subtracting $^3\text{H-TdR}$ -treated CFU-c growth from similarly treated cells not exposed to $^3\text{H-TdR}$ ("control") and dividing by "control" growth. Controls demonstrated that nonspecific toxicity was not involved. To calculate CFU-c suicide with different sources of CSA, the same treated and control cell suspensions were stimulated with PEDS and with PHA-LCM.

Velocity sedimentation at unit gravity was performed by previously published methods.^{17,18} Marrow mononuclear cell suspensions were loaded into the Sta-Put chamber (150×10^6 cells in 50 mL), followed by a linear gradient of 15% to 30% fetal calf serum in tissue culture medium. After $3\frac{1}{2}$ hours of sedimentation, 50-mL fractions were collected, cell counts and smears obtained, and assays for CFU-c performed using either PEDS or PHA-LCM for CSA.

Fig 1. Total CFU-c number when stimulated by 5% normal dog serum plus either PHA-LCM (□) or PHA added directly to dog marrow cells (■). The concentration of PHA used to stimulate blood mononuclear cells to make LCM varied from 1 to $50\text{ }\mu\text{g/mL}$ and was compared with the effect of adding the same PHA concentration directly to marrow cells. Results are expressed as mean $\pm$ SEM colony numbers per plate containing 1×10^6 nucleated bone marrow cells and assayed at days 8 through 10 (N = four experiments, each experimental point representing a mean of triplicate plates).

RESULTS

Colony stimulating activity in PHA-LCM. Initial experiments confirmed that PHA-LCM made from dog peripheral blood mononuclear cells incubated for seven days do stimulate the growth of colonies from normal dog bone marrow growing at 10 days of incubation. This is a dose-dependent stimulation with a broad plateau of activity evident from 10 to $50\text{ }\mu\text{g/mL}$ that is not due to carryover of PHA into the marrow, since direct addition of PHA to marrow cells is not stimulatory (Fig 1).

Colonies formed with PHA-LCM. Using one lot of PHA-LCM made from normal dogs with PHA at a concentration of $50\text{ }\mu\text{g/mL}$, we next examined the time course of development of macrophage and neutrophilic colonies from normal dog marrow cells. As previously shown, the colonies growing early in culture were largely macrophage colonies, whereas those growing later were a mixture of neutrophilic and macrophage colonies. Plotting colonies per plate (10^5 marrow cells), PEDS and PHA-LCM showed distinctly

Fig 2. The effect of (A) PHA-LCM and PEDS (B) on morphological subtypes of colonies at various days in culture. □, Macrophage colonies; ▨, neutrophil-containing colonies (pure neutrophil and mixed neutrophil-macrophage colonies). Results expressed as in Fig 1 (N = five experiments).

different patterns of growth, with a late-occurring burst of neutrophil-containing colonies (neutrophil and mixed) when PHA-LCM was used as the source of CSA (Fig 2).

We then explored the subtypes of colonies formed using PEDS and PHA-LCM as stimulators for gray collie dog marrow target cells and compared them with results with normal dog marrow cells. With normal dog marrow cells, PEDS stimulated a peak number of CFU-c by day 10 or 11, which then remained elevated to days 21 and 28, while PHA-LCM caused a similar rise in total colony number. Subtypes of CFU-c were then determined at day 10 and at day 16 or 17 and marked differences between PEDS and PHA-LCM were noted (Table 1). At day 10 only 11% of colonies were neutrophilic with PEDS as stimulator, whereas 26% were neutrophilic with PHA-LCM ($P < .05$). This difference was further magnified at days 16 to 17, when 2% were neutrophilic with PEDS and 59% were neutrophilic with PHA-LCM ($P < .001$) (Table 1). In general, the same features were evident using gray collie marrow cells as targets: PEDS stimulated mostly macrophagic colonies, whereas PHA-LCM stimulated more neutrophilic colonies, especially at days 16 and 17 (Table 1).

Colony-forming cell characterization. To determine whether PEDS and PHA-LCM stimulated different colony-forming cells, we layered dog bone marrow mononuclear cells over a velocity sedimentation gradient. Assays of each fraction for CFU-c stimulated by either of the stimulators demonstrated that the cell populations forming colonies had the same general patterns of sedimentation with modal sedimentation velocities of 7.1 mm/h (Fig 3).

Tritiated thymidine suicide studies to estimate the cell cycle characteristics of normal dog marrow cells stimulated by PEDS and PHA-LCM showed that CFU-c grown with PEDS had a suicide rate of $45\% \pm 7\%$ (comparable to our prior report⁷), whereas those grown with PHA-LCM had a lower suicide rate of $29\% \pm 6\%$ ($n = 4$, $P < .05$, paired t test).

Effect of lithium and PHA on cyclic neutropenic blood mononuclear cells. Initial trials showed that addition of lithium *in vitro* to peripheral blood mononuclear cells by itself did not enhance the elaboration of CSA (GM-CSA)

Fig 3. Velocity sedimentation profiles of dog CFU-c assayed at day 10 (A) and day 16 (B). Colonies formed when PHA-LCM was used as a stimulator are shown by solid symbols; PEDS, by open symbols. Modal sedimentation velocity for all CFU-c was 7.1 mm/h, while the modal sedimentation velocity for all low-density marrow cells was 4.7 mm/h (shaded area).

(data not shown). We proceeded to examine the effects of adding lithium to mononuclear cells stimulated by PHA to produce GM-CSA. Lithium at 2 mmol/L (2 mEq/L) caused no increase in CSA generation at plateau concentrations of PHA (eg, 50 $\mu\text{g/mL}$), but at submaximally stimulatory concentrations (1 and 5 $\mu\text{g/mL}$) it markedly enhanced the

Table 1. Colony Subtypes Stimulated by PEDS and PHA-LCM

Target Marrow	Stimulator	Day 10		Days 16-17

Plates were scored for percentage of subtype from each of three to 11 dog marrows; mean percentage $\pm$ SEM, n = total number of marrows assayed.

*10% vol/vol.

†PHA-LCM—phytohemagglutinin-stimulated (50 $\mu\text{g/mL}$) leukocyte conditioned medium from a single normal dog, 10% volume/volume.

‡Significantly different ($P < .05$) from colony subtypes stimulated by PEDS.

production of GM-CSA by mononuclear cells obtained from gray collies during neutrophilia (cycle days 8 through 12) (Fig 4). Neither normal dogs nor gray collies during neutropenia (cycle days 2 through 4) showed this stimulatory effect. Gray collie dogs whose cycling had been eliminated by lithium treatment in vivo likewise failed to show this enhancement by in vitro addition of lithium (Fig 5).

Inhibitor assays. Experiments were performed to determine whether addition of Li to gray collie mononuclear cells caused a reduction of an inhibitor present in the untreated (no Li) LCMs or an increase in a stimulator. One-to-one mixtures of control PHA-LCM (made by normal dog mononuclear cells stimulated with 50 $\mu\text{g}/\text{mL}$ PHA) and freshly prepared gray collie LCMs were performed. When a total of 10% LCM (5% control PHA-LCM plus 5% test PHA-LCM) was added to normal dog marrow cell targets, we found no decrease in growth compared with that expected with control PHA-LCM alone (Table 2) ($P > .30$). Parallel assays using normal dog PHA-LCMs similarly showed no evidence for inhibitors (data not shown).

Dialysis and blocking experiments. Additional studies of these conditioned media were carried out to determine that lithium carryover into the target marrow cells was not responsible for the stimulatory effect. In dialyzed conditioned media there was a slight decrease in CSA, but the same differences in stimulatory activity between lithium-treated and lithium-untreated conditioned media were readily demonstrated (Table 3). Thus, whereas at PHA concentrations of 50 $\mu\text{g}/\text{mL}$, Li had no effect on CSA in either dialyzed or undialyzed LCMs, at the lower concentrations of PHA, both dialyzed and undialyzed LCMs showed significant increases in CSA when Li was added. In addition, studies were performed in which cyclosporine was added to the mononuclear cell suspensions that were incubated to

Fig 4. Effect of lithium (2 mmol/L) on PHA-induced dog GM-CSA. PHA-LCMs were made using PHA at 1, 5, and 50 $\mu\text{g}/\text{mL}$ from normal dogs (ND) and from gray collies during neutropenia (GC 2 through 4) or during neutrophilia (GC 8 through 12), either without or with lithium (+Li). PHA-LCMs were all assayed against normal dog marrow cells and results are reported as in Fig 1 (N = seven experiments). Neutrophilic gray collie cells (GC 8 through 12) showed a significant ($P < .05$) increase when Li was added at 1 and 5 μg PHA.

Fig 5. Effect of lithium treatment in vivo on lithium responsiveness of PHA-induced dog GM-CSA. Untreated gray collie cells (GC 8 through 12) show significant ($P < .05$) increase with addition of Li at 1 and 5 μg PHA, whereas lithium-treated gray collie cells (Li-Rx GC) showed no change with addition of Li in vitro. Results presented as in Fig 1 (N = four experiments).

produce CSA. When cyclosporine was added at 3 $\mu\text{g}/\text{mL}$ in the presence or absence of lithium, there was no detectable CSA in the supernatants (Table 4). Addition of cyclosporine directly to the bone marrow assay system demonstrated no inhibitory effects (data not shown).

DISCUSSION

Previous studies of the pathogenesis of cyclic hematopoiesis in gray collie dogs have clearly shown the defect to be one of fluctuating levels of marrow cell production and have documented marked swings in the numbers of committed granulocytic progenitor cells in blood and marrow.¹⁻¹⁰ Although several studies have examined levels of putative

Table 2. Assay for Inhibitors in PHA-LCMs

	Colonies/ 10^5 Cells (n = 4)
Controls	
Without additions	24 $\pm$ 10
10% PHA-LCM (control)	53 $\pm$ 11
Test LCMs	
10% PHA-LCM—1 $\mu\text{g}/\text{mL}$	40 $\pm$ 12
10% PHA-LCM—5 $\mu\text{g}/\text{mL}$	40 $\pm$ 10
10% PHA-LCM—1 $\mu\text{g}/\text{mL}$ + Li	38 $\pm$ 13
10% PHA-LCM—5 $\mu\text{g}/\text{mL}$ + Li	41 $\pm$ 13
Mixtures (1:1, total = 10% vol/vol)	
Control + Test 1	66 $\pm$ 15
Control + Test 2	56 $\pm$ 12
Control + Test 3	55 $\pm$ 14
Control + Test 4	54 $\pm$ 14

Controls refer to cultures containing 5% normal dog serum. Test LCMs were conditioned media made from neutrophilic gray collies with 1 or 5 $\mu\text{g}/\text{mL}$ PHA with or without lithium (Li). Control refers to control above made with normal dog cells and PHA at 50 $\mu\text{g}/\text{mL}$. Two sets of freshly prepared GC PHA-LCMs were prepared and assayed a total of four times against normal dog marrow cells.

Table 3. Dialysis of Gray Collie PHA-LCM

PHA Concentration	Colonies per 10 ⁵ Nucleated Normal Marrow Cells	
	Undialyzed	Dialyzed
No Li added		
1 µg/mL	23 ± 4	22 ± 13
5 µg/mL	17 ± 3	22 ± 4
50 µg/mL	44 ± 8	30 ± 9
Li added (2 mol/L)		
1 µg/mL	40 ± 9*	31 ± 9†
5 µg/mL	C	28 ± 10
50 µg/mL	43 ± 18	34 ± 13

PHA-LCM was from "neutrophilic" gray collie cells (cycle days 8 through 12). Colony numbers are means of duplicate assays of the same dialyzed and undialyzed LCMs, representing six plates for each number, ± one SD. C, specimen contaminated during cultures.

*Significantly different from CSA of LCM made in the absence of lithium ($P < .001$, paired t test).

†Significantly different from CSA of LCM made without lithium ($P < .05$, paired t test) and from CSA of undialyzed LCM ($P < .05$).

granulocytic regulators in this disease,^{7,19,20} each has had significant drawbacks. In the earliest report, dog urine was assayed for activity stimulating murine cell proliferation and questions were raised about species specificity as well as the possibility that the "CSA" was the result of endotoxemia during neutropenia rather than being the cause of the cyclic cell production.¹⁹ In the other two reports, assays used dog marrow cell targets but did not distinguish between neutrophilic and macrophagic "CSA." In our studies the CSA being measured appeared to be the result rather than the cause of neutropenia,⁷ a finding concordant with that of Greenberg et al in the analogous human disorder.²¹ In addition, we found that serum levels of CSA were not altered by either endotoxin or lithium treatments, two therapies that

eliminate cyclic neutropenia in these dogs.^{7,12} However, the lack of neutrophilic specificity of the CSA assays that had been published suggested that a new assay was needed and led directly to the present studies of GM-CSA.

These data show that PHA stimulates dog blood mononuclear cells to produce a CSA with neutrophilic activity. This activity has characteristics similar to those reported for GM-CSF in mice and humans in that it stimulates both G and M colonies, it affects colony-forming cells that grow somewhat later in the cultures, and it appears to stimulate a different subpopulation of CFU-c than does the PEDS as defined by different ³H-TdR suicide rates.¹⁵ Because PHA stimulation is well known to stimulate lymphocyte production of GM-CSF and has been used to purify its cDNA,¹⁶ these results were not unexpected. The ability of cyclosporine to block the elaboration of this material is consistent with its ability to inhibit T lymphocyte function and block production of megakaryocytic CSA.²²⁻²⁴

Knowing that this GM-CSF-like activity (GM-CSA) was elaborated by normal dog cells, we next examined the possibility that dogs with cyclic hematopoiesis had alterations in production or responsiveness to GM-CSA. Because lithium abolishes cyclic neutropenia in these dogs, we also examined the effect of lithium in vitro and in vivo on GM-CSA generation. Gray collie dogs responded to the GM-CSA normally (Table 1) and produced comparable quantities of GM-CSA when maximally stimulated (PHA = 50 µg/mL; Fig 4). During the time of "neutrophilia" (cycle days 8 through 12), the gray collie cells produced more GM-CSA with lithium and low doses of PHA than did normals. Inhibitor assays suggest this increased activity is not due to a decrease in an inhibitor. Furthermore, when a gray collie's cycling was eliminated by lithium treatment in vivo, this augmentation of GM-CSA production was not evident (Fig 5).

Studies of the mechanism of lithium-induced granulocytosis have shown that marrow cell production is increased,²⁵ and that lithium can stimulate the production of "CSA," the production of factors other than "CSA," and the proliferation of primitive granulocytic progenitor cells by a direct although unspecified mechanism.²⁶⁻³² Lithium prevented the granulopoietic differentiation arrest caused by human leukocyte interferon and increased physical interactions between monocytes and T lymphocytes, suggesting still other possible mechanisms of action.^{33,34} Our prior studies of the mechanism of lithium normalization of cyclic hematopoiesis failed to show any alteration in "CSA" in serum¹² and in this study we did not detect differences in GM-CSA generation by mononuclear cells with lithium added in the absence of PHA. However, lithium was effective in increasing GM-CSA at precisely the time the marrow neutrophilic precursors are at their nadir, suggesting that this mechanism could be physiologically relevant.

Two other lines of evidence suggest that these findings may be important. Recently, Jones et al have shown that bone marrow adherent cells fail to produce a stimulatory factor on cycle day 9 in their dogs with cyclic hematopoiesis and that marrow cell conditioned media inhibit murine CFU-S proliferation.^{35,36} Their data do not suggest that a

lymphoid effector cell is involved, but certainly do not rule out the possibility, since the adherence procedure may trap lymphocytes as well as monocytes. The published data suggest that a lack of neutrophilic progenitor cells at the time of normal neutrophil counts is the proximate cause of the subsequent neutropenia in this disorder; a therapy that blocks an aberrant inhibitor or provides an absent stimulator at this phase of the cycle makes an attractive hypothesis. In addition, Verma et al reported studies in a patient with acquired cyclic neutropenia who responded to lithium treatment with improvement in her neutrophil counts.³⁷ In this person they implicated blocking of T lymphocyte suppression of monocyte CSA generation as being important in the lithium response.

We conclude from these studies that PHA is a useful stimulator of GM-CSA in dogs, as it is in mice and humans.

Using this form of GM-CSA, we have shown that gray collie and normal marrow cells respond by producing similar numbers and subtypes of CFU-c. In addition, the capacity of gray collie cells to increase GM-CSA levels in response to Li during the period of normal neutrophil counts is greater than that of normal dogs or gray collies treated *in vivo* with Li. These data suggest that Li-induced normalization of cyclic hematopoiesis in the gray collie could be due to intramedullary generation of GM-CSA at the critical time of deficient neutrophilic progenitor cell populations in the marrow.

ACKNOWLEDGMENT

We thank the animal and veterinary technicians of the Division of Animal Medicine for their care of the dogs; Elizabeth Hansen for technical assistance; Carole Flynn-White and Carmen M. Nott for preparation of the manuscript.

The Xerocytosis of Hb SC Disease

By Samir K. Ballas, James Lerner, Eugene D. Smith, Saul Surrey, Elias Schwartz, and Eric F. Rappaport

Patients with Hb SC disease were found to have microcytic and hyperchromic red cell indices despite mild reticulocytosis. Iron deficiency anemia was ruled out by the finding of normal serum ferritin levels. In order to determine whether the microcytosis was due to coexistent α -thalassemia, restriction endonuclease mapping was performed on genomic DNA extracted from peripheral blood leukocytes. Patients with Hb SC disease had microcytic indices despite the presence of a full complement of four α -genes ($\alpha\alpha/\alpha\alpha$), suggesting that the microcytosis may be due to cellular dehydration (or xerocytosis), since the mean corpuscular hemoglobin concentration in Hb SC disease patients was significantly higher than in controls. This possibility was investigated further by the determination of RBC cation content. RBC Na levels were similar in SC and normal red cells. Hb SC RBCs, however, had significantly reduced K levels. These findings show that RBC cation content, and

thus cell water, is decreased in Hb SC disease. The decreased RBC K level in the presence of normal cellular Na concentration suggests selective K loss that is not due to inhibition of the Na K pump. Ouabain-insensitive K^+ efflux was increased to four times normal in SC cells. Cell dehydration was confirmed by the demonstration of increased high-density RBCs on discontinuous Stratan density gradients and by osmotic gradient ektacytometry. Cellular dehydration and its sequelae were worse in CC erythrocytes and milder in AC cells than in Hb SC red cells. Taken together, these data indicate that in Hb SC disease the RBCs are severely dehydrated and typically microcytic and hyperchromic. Hb SC RBCs seem to be dehydrated due to selective K loss. These findings suggest a functional interrelationship between Hb SC, the red cell membrane, and cation regulation.

© 1987 by Grune & Stratton, Inc.

THE ANEMIA of Hb SC disease is mild and often described as normochromic and normocytic, with many target cells and "boat-shaped" or "fat" sickle cells in the peripheral smear.^{1,2} We³ and others,⁴⁻⁶ however, reported that patients with Hb SC disease typically have microcytic and hyperchromic erythrocytes. Furthermore, Fabry et al⁷ found an unusually high mean corpuscular hemoglobin concentration (MCHC) in Hb SC disease that seems to result from cellular dehydration (xerocytosis). Bunn et al⁸ also noted an abnormally high MCHC in SC cells and suggested that the presence of Hb C resulted in the high MCHC of Hb SC cells early in their lives. These studies suggest that the high MCHC may be an important contributory factor to the pathogenesis of Hb SC disease. This study was designed to elucidate the basis of cellular dehydration in Hb SC erythrocytes obtained from our current patients with this disease and determine the rheological and pathophysiologic consequences of this phenomenon.

MATERIALS AND METHODS

Patients. All patients were examined and diagnosed at the Sickle Cell Center of the Cardeza Foundation of Jefferson Medical College and Thomas Jefferson University Hospital during the past 10 years (1975 to 1985). A total of 35 patients with Hb SC disease was seen during this period. The procedures described in this paper, however, were performed on blood obtained from 16 individuals with

$\alpha\alpha/\alpha\alpha$ genotype and Hb SC disease who were being followed in our clinic while this study was in progress. All patients were American blacks. Averages of the numerous hematologic data obtained on each patient were determined. Hematologic data on transfused patients were included in this study only if determined at least 4 months after the last transfusion. Only one patient in this study was a pediatric subject, a 6-year old girl; all others were adults whose ages ranged from 20 to 60 years. Five of these patients were males. Both males and females had similar mean corpuscular volume (MCV), MCHC, and reticulocyte values, but the hemoglobin and hematocrit levels were higher in males than in females, as was previously reported.³ The three individuals with Hb AC trait were females whose ages ranged from 20 to 25 years. The patient with Hb CC disease was a 9-year old female. Control subjects were black university personnel or normal adult black individuals who came to our clinic to determine whether they were carriers of the sickle gene.

Erythrocyte preparation. Erythrocytes from patients and controls were drawn into heparin or acid-citrate-dextrose, cooled to 4 °C, and processed as follows: hemoglobin, hematocrit, red cell count, reticulocyte count, red cell electrolytes, and DNA extraction were performed on freshly drawn samples within one to two hours of collection. Cation flux experiments and ektacytometry were determined within 24 hours of collection. Other procedures were done within 24 to 48 hours of collection or as indicated. Sickle red cells suspended in citrate, phosphate, and dextrose do not exhibit a density change for five days,⁹ and therefore maintain the pattern of their distribution on discontinuous Stratan density gradients during this period. All procedures, unless otherwise noted, were performed at 4 °C. Aliquots of cells were washed at least three times in buffers as specified for the various procedures described below, and the buffy coat was removed by aspiration after each wash.

Hematologic data. Hemoglobin and reticulocyte determinations were made by routine methods and the microhematocrit was obtained by centrifugation. Red cells were counted on a Coulter Model F cell counter (Coulter Electronics, Hialeah, FL). Serum ferritin was determined by a radioimmunologic assay.¹⁰

Hemoglobin electrophoresis on starch gel, starch block, or agar gel was performed on membrane-free hemolysates by established methods.¹¹ Hemoglobin solubility testing was conducted by using a commercial assay (Sickledex; Ortho Diagnostics, Raritan, NJ). Individual globin chains were differentiated by cellulose acetate electrophoresis of membrane-free hemolysate as described by Ueda and Schneider.¹²

Determination of α -globin genotype. Alpha-globin genotypes ($\alpha\alpha/\alpha\alpha$, and $-\alpha/\alpha\alpha$) were determined by Southern blot hybridization restriction endonuclease mapping¹³ of genomic DNA extracted from peripheral blood leukocytes. The restriction endonucleases used were *Bam*HI and *Bgl*II, and the probe was *Bam*HI linearized α -cDNA plasmid JW 101¹⁴ that was ³²P-labeled with calf thymus DNA primers.¹⁵

Ektacytometric studies. The ektacytometer, a visco-diffractometer, designed and previously described by Mohandas et al^{16,17} was used to determine red cell deformability under various experimental conditions. This device imposes a well-defined laminar shear stress field on erythrocytes while simultaneously monitoring the extent of cell deformation. The instrument consists of a concentric cylindrical viscometer in which one cylinder can be rotated to produce the desired level of shear stress. A laser beam is directed through the cell suspension that is contained within a 0.5-mm gap between the two cylinders. The cells, oriented by the shear stress field, then diffract the laser beam to produce a coherent diffraction pattern, from which cell deformation is determined, using a photometric image analysis system.^{16,17} A "deformability index" (DI) is obtained that is equivalent to a measure of the ellipticity of a uniformly deforming cell population. In the standard mode of operation, the DI is recorded continuously as a function of shear rate.^{17,18} For measurement of intact cell deformability, 10 μ L of 40% red cell suspension are thoroughly mixed with 10.0 mL of polyvinylpyrrolidone (PVP; molecular weight 360,000 4 g/dL wt/vol, 97.5 cp, 290 mosm/kg, pH 7.4). This suspension produces a maximum shear stress of 170 dynes/cm² at the maximum applied shear rate of 100 rpm. Numerical values of the maximum deformability index reached, defined as DI max, were used to compare deformability of different samples.

The ektacytometer was also used to measure whole cell deformability of erythrocytes as a continuous function of the suspending medium osmolality at a constant applied shear stress of 170 dynes/cm² (osmotic gradient ektacytometry). For these studies the DI of red cells was continuously recorded as the suspending medium osmolality was increased from 50 to 700 mosm/kg as previously described.¹⁹

Separation of red cells by density. Subpopulations of erythrocytes of uniformly defined densities were isolated on discontinuous Stractan II (Champion International, Tacoma, WA) density gradients by centrifugation of normal and Hb SC cells.²⁰ The gradients covered a density range from 1.065 to 1.139 g/mL, in increments of 0.004 g/mL.

Active and passive influx of ⁸⁶Rb. Influx of ⁸⁶Rb into red cells was determined in the presence or absence of 0.1 mmol/L ouabain as previously described.^{21,22}

Potassium efflux. Red cells were washed three times in a HEPES-buffered (10 mmol/L pH 7.50) NaCl solution (290 mosm/kg) containing 5 mmol/L glucose, and the buffy coat was removed after each wash. Washed cells were resuspended at a hematocrit of 10% in the same medium, containing 0.1 mmol/L ouabain to define the ouabain-insensitive component of K⁺-efflux. After preincubation at 37 °C for 10 minutes, triplicate aliquots of cell suspension were removed at 30-minute intervals, centrifuged in a microfuge,

and the supernatants removed for subsequent analysis of K⁺ by flame photometry. Initial intracellular cation concentrations were determined on hemolysates of cell aliquots washed in isotonic Tris-buffered MgCl₂ (10 mmol/L Tris-HCl, pH 7.4, 290 mosm/kg). First-order K⁺ efflux rate constants were determined by plotting the log of the declining intracellular K⁺ concentrations, calculated from the initial and supernatant concentrations, versus time.²²

Adenosine triphosphatase (ATPase) assays. Hemoglobin-free erythrocyte membranes were prepared from red cells by hypotonic lysis and washing in 7 mmol/L NaCl, 5 mmol/L Tris-HCl, 1.0 mmol/L EDTA, pH 7.4.

The Mg⁺⁺-dependent ATPase activity was assayed in a medium containing 3.0 mmol/L ATP (disodium salt neutralized to pH 7.1), 20 mmol/L Tris-HCl, pH 7.4, 1.0 mmol/L EGTA, 0.2 mmol/L ouabain, 3 mmol/L MgCl₂, 116 mmol/L NaCl, and 16 mmol/L KCl. Ouabain was omitted when the total Na⁺-K⁺ ATPase activity was to be determined. The Na⁺-K⁺ ATPase was defined as the ouabain-sensitive component, and the ouabain-insensitive component as the Mg⁺⁺-dependent ATPase activity. Each assay tube contained 100 to 300 g of membrane protein in the presence or absence of 0.2 mmol/L ouabain in a total volume of 2.0 mL. ATP and membrane blanks were run simultaneously with incubations at 37 °C for one hour. ATPase activity was expressed as nmoles Pi liberated per milligram membrane protein per/minute by the method of Fiske and Subbarow²³ as modified by Bartlett.²⁴

Analytical methods. Red cell sodium and potassium concentrations were determined by flame photometry of red cell aliquots washed in ice-cold, isotonic Tris-buffered MgCl₂ solution (10 mmol/L Tris-HCl, pH 7.4). Red cell membrane protein content was determined by the method of Lowry et al.²⁵

RESULTS

Hematologic data. Hematologic data of the 16 patients studied with Hb SC disease and $\alpha\alpha/\alpha\alpha$ genotype are summarized in Table 1. The MCV in Hb SC disease is decreased ($P < .001$) despite mild reticulocytosis, while the MCHC is increased ($P < .001$). Iron deficiency was ruled out by the finding of normal or elevated serum ferritin in 12 patients with Hb SC on whom ferritin levels could be obtained. Thus, the red cell indices in Hb SC disease are typically microcytic and hyperchromic. Similarly, individuals with Hb AC and CC and four α -genes also have microcytic and hyperchromic indices with no iron deficiency.

α -Globin genotype. Restriction endonuclease mapping of genomic DNA showed that the 16 patients with Hb SC disease, the three individuals with Hb AC, and the patient with Hb CC had normal α -globin genotype ($\alpha\alpha/\alpha\alpha$).

Red cell cation content. The hydration status of Hb, SC, AC, and CC erythrocytes was studied by determining the red cell cation content, cell distribution on discontinuous Stractan density gradients, and osmotic gradient ektacytometry.

Values shown are mean $\pm$ SD. Number of individuals on whom the indicated parameter could be performed is indicated in parentheses.

*Number is average of five determinations.

Table 2. Cation Concentration and Content of Normal and Hb SC, AC, and CC Cells

RBC	mEq/L RBC			mEq/10 g Hb		
	Na ⁺	K ⁺	Na ⁺ + K ⁺	Na ⁺	K ⁺	Na ⁺ + K ⁺
Control (11)	7.2 ± 1.35	103.2 ± 4.42	110.4 ± 5.05	0.22 ± 0.04	3.15 ± 0.21	3.37 ± 0.23
Hb SC (16)	9.6 ± 2.95	89.5 ± 5.16	99.2 ± 3.13	0.26 ± 0.08	2.50 ± 0.15	2.76 ± 0.12
Hb AC (3)	6.5 ± 1.08	100.2 ± 2.08	106.6 ± 2.72	0.19 ± 0.03	2.86 ± 0.10	3.04 ± 0.11
Hb CC *(1)	9.0	84.0	93.0	0.25	2.48	2.73

Values shown are mean ± SD. Number of determinations is indicated in parentheses.

*Values are averages of three determinations.

The cation content of normal and abnormal erythrocytes is summarized in Table 2. The Na content of abnormal cells was similar to controls, while the K content was significantly decreased. Noteworthy is that Hb SC and CC erythrocytes had the lowest K⁺ level, whereas AC cells had a K⁺ level that was intermediate between control and SC and CC RBC.

Distribution of Hb SC cells by density. Cellular dehydration in Hb SC, AC, and CC cells was confirmed by the presence of increased high-density cells after centrifugation on discontinuous Stratan density gradients (Fig 1). There is a shift in SC and CC cell population to higher density. Hb AC cells, again, are intermediate between controls on the one hand and SC and CC cells on the other hand.

Monovalent cation fluxes in SC cells. Various components of monovalent cation fluxes were measured to provide further information about cation regulation in Hb SC cells. ⁸⁶Rb influx in the presence or absence of 0.1 mmol/L ouabain indicated that the total influx of Rb was moderately increased in Hb SC cells while the ouabain-insensitive (passive) influx was similar in control and Hb SC RBC (Fig 2). The ouabain-sensitive influx of Rb, which represents the active pump-mediated component, was also moderately increased in SC cells as compared with controls. Measurement of ATPase activity in membrane preparations from SC cells showed mildly increased Na-K ATPase and Mg ATPase activities (Table 3).

In order to investigate the nature of the abnormality in cation regulation in Hb SC erythrocytes further, we determined the ouabain-insensitive K⁺ efflux in the presence or absence of 1.0 mmol/L piretanide or furosemide, inhibitors of Cl⁻ transport and chloride-dependent K⁺ flux. Figure 3 shows that SC cells had a markedly increased K efflux. The first-order rate constant for K efflux for SC cells was 0.043 h⁻¹, compared with 0.012 for control cells (258% increase). The addition of 1.0 mmol/L piretanide or furosemide to the medium reduced the rate constant for K efflux of normal cells by 16% to 20%, respectively, but did not decrease that of SC cells (Table 4). Table 4 also shows that K⁺ efflux from CC erythrocytes was even greater than that from SC cells. AC erythrocytes showed K⁺ efflux values that were intermediate between SC and control red cells. Again the addition of piretanide or furosemide did not reduce the K⁺ efflux from AC and CC cells.

Ektacytometric studies. In order to further elucidate the hydration status and surface area-volume ratio in SC, AC, and CC erythrocytes and their subpopulations, we studied these cells by osmotic gradient ektacytometry as previously described.¹⁹ Figure 4A shows the deformability profile of

Fig 1. The density of RBC from individuals with Hb Sc. The percentage of RBC from fractions of the analytical Stratan gradients is shown on the Y-axis and the densities of the gradient layers on which each fraction stopped are shown on the X-axis. RBC are from (A) control subjects with Hb A and four α -globin genes, (B) Hb SC patients with four α -globin genes, (C) a patient with Hb CC disease and four α -globin genes, and (D) Hb AC individuals and four α -globin genes. The horizontal lines indicate the mean value for each set of values. The inset shows representative actual density profiles from (A), (B), (C), and (D) described above.

Fig 2. ^{86}Rb influx into control and Hb SC red cells. Erythrocytes were incubated at 37°C in glucose phosphate-buffered saline containing 5 mmol/L K and ^{86}Rb in tracer quantities, in the presence or absence of 0.1 mmol/L ouabain.

total SC cells from patients with four α -genes. Although the DI values of SC cells at 290 mosm are less than those for control cells, there is a wide range of variation in the shape of the curve among the patients studied. The range shown in Fig 4A is based on 40 ektacytometric studies on cells from 16 patients with four α -genes. The shape of the curve for each patient was the same when determined on blood samples drawn at different time periods. The curves of all patients were substantially shifted to lower osmolality compared with normal curves. This finding was shown previously to indicate red cell dehydration.^{17,19} Figure 4B shows the deformability profile of erythrocytes from three individuals with Hb C trait and four α -globin genes and one patient with Hb CC and four α -globin genes. Hb CC erythrocytes showed severe dehydration as indicated by shift of the curve to very low osmolality. The curves of Hb AC cells indicate less severe dehydration than those of CC erythrocytes, and they fall within the range of the curves for SC cells shown in Fig 4A.

Because the average maximum DI of SC cells represents a heterogeneous mixture of cells covering a broad MCHC range, we next obtained osmotic gradient deformability profiles on erythrocyte subpopulations of the same density isolated on preparative Stractan gradients from one patient with Hb SC disease, another with Hb CC, and a third with Hb AC. Figure 5 shows that all curves are shifted to lower osmolality compared with the normal range. Each Stractan fraction is shifted to lower osmolality, and the degree of this shift increases as one moves from AC to SC and CC cells. Thus Hb CC subpopulations have the lowest DI and are shifted to lowest osmolality values. Table 5 also shows that the cation content of each Stractan fraction decreases as one

Fig 3. Kinetics of ouabain-insensitive K^+ loss from freshly drawn control and Hb SC red cells. Erythrocytes were incubated at 37°C in 10 mmol/L HEPES, pH 7.5, 5 mmol/L glucose, 0.1 mmol/L ouabain, and NaCl to bring the final osmolality to 290 mosm/kg. At intervals, aliquots were removed, K^+ concentration in supernatants were determined, and the first-order rate constants for K^+ efflux were calculated.

compares normal, SC, AC, and CC erythrocytes. Hb AC subpopulations have a total cation content that is intermediate between control RBC and other variant cells. Although Hb CC fractions seem to have slightly higher K^+ content than do SC cells, they are nevertheless more dehydrated than SC RBC. We attribute this difference to their much higher reticulocyte count, which, because of the lower cell Hb content, gives a higher K^+ level when it is expressed relative to Hb content. Noteworthy in Fig 5 is that reticulocyte-rich RBC fractions (density = 1.070) had lower maximum deformability than was expected for these low-density RBC.

DISCUSSION

In this study we have found that erythrocytes in Hb SC disease are dehydrated and typically microcytic and hyperchromic. The combination of relatively low MCV and an increased MCHC is unusual and seems to be characteristic of Hb SC disease.³⁻⁶ We must emphasize that red cell indices were determined by using manual methods for the determination of hemoglobin and hematocrit and the Coulter Counter Model F for the estimation of the red cell count. Mohandas et al²⁶ have shown that for MCHC values above 36 g/dL as measured by the spun hematocrit method, electronic counters (Coulter S, Coulter S-Plus, and Ortho ELT-8) underestimated the MCHC with increasing error as the true MCHC increased. The choice of the methods to determine red cell indices may explain why some reports²⁷ did not emphasize the hyperchromic nature of RBC in Hb SC disease. Fabry et al⁷ have shown that the MCHC in Hb SC disease is unusually high by using a Percoll-Stractan continuous-density gradient. They found that Hb SC cells are much denser than normal cells, and they estimate an average MCHC of 36.4 ± 0.76 g/dL on the basis of the cell distribution on the gradient. Bunn et al⁸ determined the

Cells were incubated for two hours at 37 °C in 10 mol/L HEPES (pH 7.5), 5 mol/L glucose, 0.2 mol/L ouabain, and NaCl to bring the final osmolality to 290 mos/kg, in the presence or absence of the indicated additive. Values shown are the negative 1n of the calculated intracellular K concentration as a function of time. Values shown are mean ± SD. Number of determinations is indicated in parentheses. Results were corrected for the small amount of hemolysis that occurred during incubation.

distribution of AA, AS, SC, AC, and CC RBC on discontinuous Stractan gradients and found increased proportions of dense cells whenever Hb C was present. Our findings agree with these previous reports and furnish new data on Hb SC RBC from a relatively large number of patients that include passive K permeability and pump activity, Na-K ATPase, rheologic measurements that reflect the properties of individual cells (as opposed to bulk viscometric methods), and deformability measurements on Stractan gradient subpopulations.

Microcytosis in Hb SC disease seems to be secondary to cellular dehydration. This was demonstrated by the finding of decreased cation content of SC cells, by the presence of a high percentage of dense cells on Stractan gradients, and by osmotic gradient ektacytometry. Dehydration of SC cells seems, in turn, to be due to high and selective efflux of cellular K⁺ that is not inhibited by ouabain, piretanide, or furosemide. This severe dehydration results in decreased cell volume and increased surface area-volume ratio, which explains the decreased osmotic fragility of SC cells shown by osmotic gradient ektacytometry. Thus AC red cells are least affected and CC cells are the most dehydrated. Brugnara et al²⁸ have recently reported some similar findings in RBC homozygous for Hb CC. These cells were found to contain less cations and water than did normal RBC due to an increase in K⁺ efflux that was insensitive to ouabain and bumetanide, but dependent on cell volume and internal pH.

Microcytosis in Hb SC disease does not appear to be secondary to coexistent iron deficiency anemia or α-gene

deletion, since serum ferritin levels were within the normal range or elevated in all patients on whom this test was determined. Patients with four α-genes had microcytic and hyperchromic indices. Glader et al²⁹ also indicated that even in sickle cell anemia there is "relative microcytosis," since the MCV values in this disease are less than expected for the degree of reticulocytosis. An unusual observation in this study is that reticulocyte-rich SC fractions had lower DI than expected from their low MCHC. A similar observation in reticulocyte-rich fractions from sickle cell erythrocytes was reported by Kaul et al.³⁰ The mechanisms responsible for this observation are unknown. Lack of membrane remodeling due to functional asplenia in these patients may be one possibility.

Factors responsible for the K⁺ efflux in Hb SC disease are not known. One possibility may relate to the high affinity of Hb C for the erythrocyte membrane.³¹ Preferential binding of β^C chains to red cell membranes in comparison to β^A and β^S globin polypeptides has been reported.^{32,33} The high affinity of Hb C for the red cell membrane seems to be similar to that reported for the glycolytic enzymes aldolase and glyceraldehyde-3-phosphate dehydrogenase.^{34,35} It is believed that hemoglobin binds to the cytoplasmic portion of band 3 of the red cell membrane,³⁶⁻³⁸ since it competes with the binding of glycolytic enzymes to the membrane. Binding to the membrane in each case is specific and primarily electrostatic, since it is highly sensitive to ionic strength and pH.^{34,39} Moreover, the composition of the NH₂-terminal of band 3 in human cells is very acidic. The first 31 amino acid residues

Fig 4. Osmotic deformability profile for control and Hb SC red cells. The shaded area represents the range for normal controls. (A) represents the range of 40 determinations on RBC from 16 patients with Hb SC disease and (B) represents deformability profiles on subjects with Hb AC (Nos. 1, 2, 3) and Hb CC disease (No. 4). All individuals had αα/αα genotype.

RBC are from (A) Hb SC patient, (B) Hb AC individual, and (C) Hb CC patient.

contain 16 aspartic and glutamic acid residues, no basic residues, and a blocked α -amino group.^{40,41} This composition may explain the electrostatic mode of band 3 binding to Hb C, presumably to the basic lysine residue, which replaces glutamic acid normally present at the sixth position of the β -polypeptide chain.

*Density of the Stractan layer on which each cell subpopulation rested.

Taken together, our data suggest a functional interrelationship among Hb SC, membrane stability, and cation regulation. The pathophysiologic sequence of events in Hb SC disease may be as follows: Hb SC interacts with the membrane (probably band 3), somehow increasing K⁺ efflux. Cellular dehydration ensues, with concomitant increase in MCHC and abnormal rheological properties. Microcytosis is probably also a consequence of cellular dehydration. As has been shown for Hb CC cells,²⁸ the cell membrane permeability may be modulated by the hydration status of Hb SC RBC. Thus the more dehydrated the cells, the greater is their K⁺ efflux due to increased membrane permeability. This sequence of events seems to be milder in AC cells and worse in CC erythrocytes than in SC red cells. The exact mechanisms involved in this sequence of events remain to be determined.

ACKNOWLEDGMENT

We are grateful to the Hoechst-Roussel Pharmaceutical Corporation, Sommerville, NJ, for a gift of piretanide and furosemide and to Dr Margaret R. Clark for her comments, suggestions, and critical review of this paper.

7q32-q36 Translocations in Childhood T Cell Leukemia: Cytogenetic Evidence for Involvement of the T Cell Receptor β -Chain Gene

By Susana C. Raimondi, Ching-Hon Pui, Frederick G. Behm, and Dorothy L. Williams

Blast cell chromosomal rearrangements involving the long arm of chromosome 7 were identified in eight of 197 cases of childhood acute lymphoblastic leukemia (ALL). Breakpoints were variable but tended to cluster in either the proximal or the terminal 7q region, depending on the immunophenotype of the cells. The 7q32-q36 region, the locus of the T cell receptor β -chain gene, was the site of breakpoints in four of 31 cases of T cell ALL but was not involved in any of the 166 cases originating from B cell precursors ($P < .0004$). In three of the four T cell cases it was possible to identify the chromosomal segment that had been translocated to the 7q32-q36 region: 1p32, 2p21,

and 6p21. The 1p32 and 6p21 bands are particularly interesting, as they contain the sites of two known proto-oncogenes, *c-L-myc* and *hpim*, respectively. Our findings suggest that the locus of the β -chain gene of the T cell receptor is a preferential site for certain chromosomal rearrangements in leukemic T lymphoblasts, analogous to the T cell receptor α -chain gene on human chromosome 14. Translocation of proto-oncogenes to a site near the β -chain regulatory sequences provides a potential mechanism for oncogene activation.

© 1987 by Grune & Stratton, Inc.

CERTAIN CHROMOSOMAL translocations are specific for particular subtypes of human leukemia and lymphoma.¹ The most striking example can be found in B cell neoplasias, in which translocations involve chromosomal regions containing the immunoglobulin (Ig) kappa, mu, and lambda chain genes.^{2,3} These rearrangements consistently bring the *c-myc* proto-oncogene, on chromosome 8(q24), to a position adjacent to a rearranged and transcriptionally active Ig gene, leading to aberrant activation of *c-myc*.⁴ This model of gene activation has motivated a search for other instances of consistent chromosomal rearrangements that bring an "inactive" oncogene near "activating" sequences elsewhere in the genome.⁵

The organization and rearrangement of T cell receptor (TCR) genes during T cell differentiation are analogous to the changes seen in Ig genes in B cell precursors.^{6,7} Three classes of TCR-specific cDNA clones (α , β , and γ) have been isolated.^{8,9} The gene encoding the α -chain of the TCR has been mapped to bands q11-q12 of chromosome 14,^{10,11} a locus that is nonrandomly involved in translocations and inversions in human T cell neoplasias.¹²⁻¹⁷ Moreover, molecular alterations of the α -chain locus have been demonstrated in blast cells with the t(11;14)(p13;q13) in two cases of childhood T cell acute lymphoblastic leukemia (T-ALL)^{18,19} and in a T cell line with t(8;14)(q24;q11) derived from a child with T-ALL.²⁰ In a pediatric T cell leukemia line, inversion of chromosome 14 involving bands q11 and q32 resulted in the recombinational event of the Ig heavy-chain gene (14q32) with the gene for the TCR α -chain (14q11).^{21,22} These studies suggested that the α -chain gene locus may participate in proto-oncogene activation, in a manner similar to that seen in B cell lymphoid malignancies.^{4,5} The locus for the TCR β -chain gene has been assigned to region 7q32-q36 of chromosome 7.²³⁻²⁵ Recently, Brito-Babapulle et al²⁶ observed a strong correlation between the presence of a 7q abnormality and expression of the T cell growth factor receptor (Tac) in adult T cell leukemias, leading them to speculate that the chromosomal defect is indirectly responsible for activation of the Tac gene. Finally, 7p15, where the human gamma-chain genes of the TCR is located,²⁷ is a frequent site of chromosome breakage in ataxia telangiectasia, a T cell disorder.²⁸

We present cytogenetic evidence that translocations involving the q32-q36 region of chromosome 7 are nonran-

domly associated with childhood T-ALL and suggest that the TCR β -chain locus is affected by these chromosomal rearrangements.

MATERIALS AND METHODS

Patients. From August 1983 to December 1985, 227 consecutive children with newly diagnosed ALL were admitted to St Jude Children's Research Hospital. Thirty-three cases had a T cell immunophenotype, as judged from surface antigen reactivity with various T cell-related monoclonal antibodies. One hundred ninety-seven patients, including 31 with T-ALL, had blast cell metaphase preparations adequate for cytogenetic analysis. All patients were enrolled in studies that included a cell profile analysis, approved by the institution's clinical trials committee. All patients were advised of the procedures and attendant risks, in accordance with institutional guidelines, and informed consent was obtained in each instance.

Cytogenetic studies. Bone marrow samples, obtained from patients at the time of diagnosis, were processed according to the method of Williams et al.²⁹ Briefly, 0.1 to 0.2 mL of heparinized bone marrow was collected in tubes containing 8 mL of RPMI-1640 with L-glutamine, antibiotics, and 30% fetal calf serum. The cells were processed immediately after a 25-minute incubation in Colcemid (final concentration, 0.06 μ g/mL), rinsed twice in Hank's balanced salt solution, and exposed to a hypotonic solution (0.075 mol/L KCl) for a total of 32 minutes at room temperature, including periods of mixing, standing, and centrifugation. The cells were then

fixed in methanol-acetic acid (3:1, vol/vol) for 15 minutes. Slides were prepared with use of a flaming technique and were allowed to age for zero to seven days. Metaphase preparations were G-banded by a modification of the trypsin method of Seabright,³⁰ and chromosomes were identified and assigned according to the International System of Human Cytogenetic Nomenclature.³¹

Immunophenotyping. Blast cells were separated on a density gradient, and only samples containing >85% blasts were assayed. Cell surface antigens were detected by a standard indirect immunofluorescence assay that relied on monoclonal antibodies to the major clusters of differentiation (CD) antigens described by the First and Second International Workshops on Human Leukocyte Differentiated Antigens.³² These included J5 (CD-10), anti-HLA-DR, OKT10, OKT9, 3A1 (CD-7), T101 (CD-5), T11 (CD-2), T3 (CD-3), T6 (CD-1), T4 (CD-4), T8 (CD-8), and B4 (CD-19). Two hundred cells were counted in each immunofluorescence assay; the results were considered positive if 40% or more of the blasts showed surface fluorescence. Cell surface immunoglobulin (sIg) was identified by a direct immunofluorescence assay with fluoresceinated goat antihuman immunoglobulin (Tago, Burlingame, CA). Cytoplasmic immunoglobulin (cIg) was identified by a direct method that used fluoresceinated F(ab')₂ goat antihuman μ -chains (Southern Biotechnology, Birmingham, AL).³³ Terminal deoxynucleotidyl transferase (TdT) was identified by use of an indirect immunofluorescence assay (Supertechs, Inc, Bethesda, MD).³⁴ The samples were classified phenotypically according to the patterns of reactivity as T cell (T⁺, E rosette⁺, HLA-DR⁺), common (CALLA⁺, HLA-DR⁺, E⁻, T⁻, cIg⁻, sIg⁻), pre-B cell (cIg⁺, HLA-DR⁺, CALLA⁺, E⁻, T⁻), or B cell (sIg⁺).

RESULTS

Chromosomal rearrangements involving the 7q arm were found in blast cells from eight of the 197 cases studied. The breakpoints in four of these cases occurred in the proximal 7q

region (two at 7q11 and two at 7q22), while in the remainder they were within the terminal 7q region (one at 7q32 and three at 7q36). The former group comprised three cases of common ALL and one of pre-B-ALL, whereas each of the latter four was classified as T cell ALL: common or mid-thymocyte stage (cases 1 and 3) and immature or early thymocyte stage (cases 2 and 4) (Table 1). Thus the terminal 7q region was involved in translocations within T lymphoblasts but not in those within non-T cells (four of 31 cases v zero of 166, $P < .0004$ by two-tailed Fisher's exact test). In T cell cases, the DNA material exchanged with the 7q32-q36 was different in each case (Fig 1 and Table 2), and none of the additional structural or numerical chromosomal abnor-

malities were alike except for a deletion of the p arm of chromosome 9 in cases 1 and 2.

The clinical and laboratory features of patients with T cell ALL and a 7q32-q36 translocation are summarized in Table 1. These three boys and one girl ranged in age from 9 to 17 years (median, 11.5 years). All four had a mediastinal mass, and two had central nervous system leukemia at diagnosis. Patient 1 also presented with multiple scalp nodules and right facial paralysis, and patient 4 had an epidural tumor, resulting in paraparesis at diagnosis. Three of the patients entered complete remission and two remain free of leukemia for 10+ and 28+ months. Patient 3, who failed to achieve remission, was unusual in that there was a "lineage switch" from T cell ALL to acute myeloblastic leukemia after 3 weeks of induction therapy. At that time, cytogenetic analysis disclosed only normal diploid karyotypes.

DISCUSSION

Numerical abnormalities of chromosome 7 are common in hematologic disorders, but structural abnormalities of the 7q arm are identified much less often.¹ Cytogenetic analysis of 197 well-banded consecutive cases of childhood ALL in this study disclosed eight cases with rearrangements of the 7q arm. Breakpoints were variable but tended to show specificity for the immunophenotype of blast cells. In cases of T cell disease, breakpoints were restricted to the terminal 7q region (one at 7q32 and three at 7q36), whereas in B cell-precursor cases, they occurred in the proximal 7q region (two at 7q11 and two at 7q22).

The 14q11-q12 region, which contains the TCR α -chain gene,^{10,11} appears to be nonrandomly rearranged and presumably is involved in proto-oncogene activation in T cell neoplasias.^{13,18-22} Heretofore, the 7qter region (to which the TCR β -chain gene has been mapped) has received less attention as an important site of chromosomal abnormalities in T cell malignancies.^{1,35-37} Studying the blast cell chromosomes of a large number of childhood ALL cases has allowed us to demonstrate that 7qter abnormalities represent yet another subgroup of cytogenetic abnormalities that correlates with a

specific immunophenotype of ALL. In two of our cases, there was a loss of chromosome material from the short arm of chromosome 9(p21-p22), a finding previously reported in T cell lines,³⁷ as well as a distinct subtype of ALL characterized by "lymphomatous" features and presumably of T cell origin.³⁸ However, in a collaborative study, this chromosomal abnormality was found to bear no consistent relationship with blast cell immunophenotype or other presenting features.³⁹

Chromosome bands involved in each of the reciprocal translocations with the 7q32-q36 region were 1p32, 2p21, and 6p21. The 1p32 belongs to the region to which c-L-myc⁴⁰ has been mapped. Although no specific proto-oncogenes have been identified at 2p21, Brownell et al⁴¹ have recently isolated and localized human cellular *rel* sequences to chromosome 2. The related viral sequence, r-*rel*, was derived from the cellular genome of a turkey with leukemia induced by the reticuloendotheliosis virus. Finally, the oncogene *hpim* has been mapped to the 6p21 region.⁴² The *hpim* is a human homolog of a murine gene that is activated by retroviral insertion in murine T cell lymphomas. It seems reasonable to suggest that the c-L-myc, *hpim*, and other putative proto-oncogenes are deregulated as a consequence of their translocation to a position near the TCR β -chain gene and its regulatory sequences. Whether or not the gene encoding the β -chain of the TCR is involved in the genesis of childhood T cell ALL needs to be tested by molecular analysis of the DNA adjacent to breakpoints of the 7q32-q36 translocations.

NOTE ADDED IN PROOF

Since initial submission of the manuscript we have identified another T cell ALL case with a t(6;7)(q24;q36), strengthening the association of the 7qter region with T cell malignancies.

Different Stimulative Effects of Human Bone Marrow and Fetal Liver Stromal Cells on Erythropoiesis in Long-Term Culture

By Ineke Slaper-Cortenbach, Rob Ploemacher, and Bob Löwenberg

The factors determining the predominantly erythroid direction of human fetal liver hematopoiesis are unknown. We compared the capacities of human fetal liver and bone marrow stromas to sustain fetal and adult hematopoiesis in long-term cultures. In various marrow-fetal liver combinations of stroma and recharge, the maintenance of erythroid (BFU-e) and myeloid (CFU-GM) precursors in the nonadherent phase was determined. The morphology of the fetal liver nucleated cells during culture was also examined. This study shows that fetal liver stromas efficiently support fetal BFU-e for 6 to 7 weeks in vitro. Bone marrow stromas

were not able to maintain fetal BFU-e beyond 4 weeks. Significant numbers of marrow BFU-e were not sustained in vitro on either source of stroma. On the other hand, the stroma layers of fetal liver and marrow origin were equally effective in maintaining fetal CFU-GM and adult CFU-GM in long-term culture. These findings show that the human embryonic liver stroma is a preferential site for stimulating fetal erythropoiesis. They do not demonstrate differences in stroma function to explain the relative paucity of myelopoiesis in the fetal liver.

© 1987 by Grune & Stratton, Inc.

FROM THE SIXTH until the 23rd week of gestation, the fetal liver is the main site of hematopoiesis of the human embryo.^{1,2} Although hematopoiesis is almost entirely erythroid, there is a high concentration of myeloid progenitor cells (CFU-GM) in early trimester human fetal livers, similar to that in adult bone marrow.¹ In midtrimester fetuses,² the organ continues to mainly show active erythropoiesis, despite the high frequency of CFU-GM in the tissue.

After regression of hematopoiesis in the liver, the stem cells migrate to the bone marrow, where hematopoiesis becomes established. The questions why erythropoiesis dominates in the fetal liver notwithstanding the large numbers of myeloid precursor cells and why at a certain time during ontogeny hematopoiesis settles in the bone marrow have not been clarified. These phenomena may be caused, for example, by alterations in the properties of the stem cells during prenatal development or by changes of the environmental properties of the stroma that sustain and govern hematopoietic stem cell differentiation. In order to throw light on these questions, we have performed long-term cultures according to Dexter et al.^{3,4}

Fetal liver and bone marrow-derived stroma layers were established and then seeded with fetal liver or bone marrow cells. The effects of the stroma layers, derived from either source, on the proliferation and differentiation of human fetal and adult marrow progenitor cells were assessed.

MATERIALS AND METHODS

Human fetal liver cells and bone marrow cells. Midtrimester fetuses (12 to 22 weeks) were obtained after vaginal termination of the pregnancy by the dilatation and evacuation method of Finks.⁵ Fetal age was estimated from the duration of amenorrhea and verified by echoscopy. The livers were collected in sterile Hanks' balanced salt solution (HBSS), supplemented with HEPES and antibiotics, and transported to the laboratory. Within one to three hours after collection, the livers were washed three times with HBSS, and a single-cell suspension was prepared by pressing the cells through a nylon filter. The cells were passed through an 0.8-mm needle and filtrated through a Jena glass filter (D2, 90 to 40 μ m). The nucleated cells were counted in Türk solution. The viability was estimated by trypan blue exclusion and varied between 65% and 85%.

Bone marrow cells were aspirated from the posterior iliac spine of adult volunteers who had no hematologic abnormalities. The nucleated marrow cells were separated after 0.1% methylcellulose

sedimentation. All patients had given informed consent to donate marrow in accordance with institutional guidelines.

Parts of the fetal liver and bone marrow cells were directly used for preparing adherent stroma layers in culture; the remainders of the cell suspensions were cryopreserved.

Long-term cultures. Bone marrow stroma layers, derived from 20×10^6 nucleated marrow cells per flask, were established during 2 to 3 weeks in 8 mL of alpha medium containing 20% horse serum and 10^{-7} mol/L hydrocortisone acetate as described by Touw and Löwenberg.⁶ Fetal liver adherent cell layers were established during 3 to 5 weeks after inoculation of 15×10^6 nucleated fetal liver cells into T flasks. After stroma formation, the fetal liver and bone marrow cells were thawed and separated on Ficoll Isopaque (1.077 g/mL). Then 5 to 10×10^6 of these nucleated cells were inoculated in cultures in which stroma layers had been preestablished. Cultures were run in duplicate. Various combinations of stroma layer and recharge were examined in comparative experiments: autologous fetal liver cells on a fetal liver stroma, allogeneic fetal liver cells on a fetal liver stroma, allogeneic fetal liver cells on a bone marrow stroma, and allogeneic bone marrow cells on a fetal liver stroma. To exclude the possibility that the progenitors arose from the adherent cell layer, in selected experiments the stroma layers were irradiated (25 Gy) before recharge. Control experiments were also performed by culturing fetal liver cells in the absence of a stroma layer. At weekly intervals the nonadherent cells, in the collected half-volume of the culture medium, were counted and assayed for myeloid and erythroid progenitor cell content (CFU-GM, BFU-e), and the medium was replaced by fresh medium. The number of progenitor cells are expressed as the total number per flask and the values are corrected for weekly half-volume depletion ($A \times 2^{n-1}$, A = number of recovered progenitor cells as determined in two flasks, n = number of weeks in culture). In selected experiments, the morphology of the cells was examined as well.

Colony-forming assays. Granulocyte-macrophage colonies were grown in a double layer semisolid agar system, supplemented with 20% to 30% human placental conditioned medium (HPCM) in

the underlayer, as described,⁶ to determine the number of myeloid precursors (CFU-GM). Erythroid burst-forming units (BFU-e) were cultured in 1.1% methylcellulose in Iscove's modified Dulbecco's medium (IMDM; GIBCO, Scotland), supplemented with crude human urinary erythropoietin (prepared from urine of patients with aplastic anemia), 30% fetal calf serum, bovine serum albumin (0.75%), egg lecithin (3×10^{-5} mol/L), Na_2SeO_3 (10^{-7} mol/L), iron-saturated human transferrin (7.7×10^{-6} mol/L), and beta-mercaptoethanol (5×10^{-5} mol/L). One milliliter of this culture medium, containing 1×10^5 marrow or fetal liver cells, was plated into four wells of a cluster dish (Costar, Cambridge, MA; 16-mm well diameter) and incubated at 37 °C in a fully humidified atmosphere with 5% CO_2 in air. Colonies containing more than 50 cells were counted on day 14 by use of an invertoscope (Zeiss).

The number of CFU-GM and BFU-e per 10^5 cells in the fetal liver preparations of varying embryonic ages at the time of collection were determined. Early and late midtrimester fetal livers contained approximately equivalent concentrations of precursor cells. Fetal age 13 to 15 weeks: CFU-GM = 694 ± 309 ($n = 26$) (mean $\pm$ SD), BFU-e = $3,917 \pm 2,420$ ($n = 14$); 16 to 18 weeks fetal age: CFU-GM = 754 ± 397 ($n = 34$), BFU-e = $4,166 \pm 2,009$ ($n = 20$).

Cell morphology. In order to follow the lineage-specific maturation during long-term culture, in some experiments the cells were used for cytological examination. Samples of the nonadherent cells were collected, cytocentrifuged (Shandon, Cheshire, England) and stained with May-Grünwald-Giemsa (Merck). Per differential count, 200 cells were scored. Fetal liver and bone marrow stromal layers were also examined after cytochemical staining with α -naphthyl-esterase (with and without sodium fluoride), alkaline phosphatase, and acid phosphatase.

RESULTS

The ability of fetal liver stroma layers to maintain fetal liver cells in Dexter-type cultures. In six experiments (Table 1) we recharged fetal liver-derived adherent cell

layers with cryopreserved autologous fetal liver cells, to determine the maintenance of CFU-GM and BFU-e in long-term culture. A typical decline of CFU-GM numbers was seen in all instances during the first week, which, in four experiments, was subsequently followed by a maintenance of CFU-GM during another 5 to 6 weeks. In four experiments CFU-GM numbers were still detectable at week 6 to 7 of culture, while in the two other experiments (2 and 6) CFU-GM extinguished rapidly. Numbers of BFU-e were also assessed throughout culture and were recovered until approximately week 6 of culture. BFU-e showed similar kinetics of recovery in vitro, ie, a precipitous fall during week 1 and a maintenance of BFU-e numbers during the subsequent 6 weeks of culture. The data are not indicative of a relationship between fetal age of the stromas and their capacity to support CFU-GM and BFU-e during culture. Stromas derived from livers of week 14 and week 15 fetuses (Table 1, experiments 1, 2, and 3) and those from week 18 (Table 1, experiments 4, 5, and 6) gave equivalent results.

In order to investigate the capacity of fetal liver stroma layers to sustain the fetal liver hematopoiesis from different donors, we also evaluated the effect of allogeneic stroma layers under similar conditions. Two directly comparative experiments were performed, and the influence of the allogeneic fetal liver stroma on the recoveries of nucleated cells, CFU-GM, and BFU-e in long-term cultures was determined. Equivalent values of these parameters were measured on allogeneic and syngeneic fetal liver stroma layers.

In addition, four control experiments were performed in which fetal liver cells were cultured in the absence of a stroma layer. In these cultures no CFU-GM and BFU-e could be recovered at week 4 of culture. In two experiments, the cell layers were scraped and assayed for the presence of

The upper part of the table presents the recoveries of CFU-GM numbers; the lower part, those of BFU-e numbers during long-term culture. Figures indicate corrected numbers of progenitors per flask. ND, not determined.

*Fetal age in weeks.

CFU-GM and BFU-e. This was done to verify whether significant numbers of progenitor cells were trapped in the adherent cell layer. At week 3 of culture, the fetal liver stroma layer contained 75 CFU-GM per flask and at the time of recharge (week 4) no CFU-GM were detected. At the same time points, no BFU-e were measurable in the fetal liver adherent cell layers.

Is the bone marrow stroma layer capable of maintaining allogeneic fetal liver cells in long-term culture? In a subsequent series of experiments, a comparison between the effects of bone marrow and fetal liver layers on fetal liver CFU-GM (Fig 1) and BFU-e (Fig 2) was made. These experiments were performed using allogeneic cells.

The myeloid progenitor cells from fetal liver were equally well maintained on fetal liver and bone marrow stroma layers until approximately week 9. No differences were seen as compared with cultures in which the stroma layers had been preirradiated, indicating that the CFU-GM measured in the nonadherent layer were not derived from the adherent layer. On the other hand, it appeared that bone marrow adherent cell layers were generally inferior to fetal liver stroma layers in maintaining fetal liver BFU-e numbers. This was apparent from the directly comparative experiments presented in Fig 2. Additional experiments revealed that considerable numbers of BFU-e were still recoverable at week 6 in five allogeneic fetal liver cultures (data not shown). However, when allogeneic fetal liver cells were cultured on a bone marrow stroma layer, BFU-e were measurable until 3 to 5 weeks only.

Thus these data indicate a stromal specificity of fetal liver and adult marrow for promoting the recoveries of the erythroid precursor cells but not myeloid precursor cells. Notably, preirradiation of the stroma layers did not influence the recoveries of the numbers of BFU-e from the cultures.

Is a fetal liver stroma layer also capable of maintaining

Fig 1. Direct comparison of the effect of fetal liver and bone marrow stromas on fetal liver CFU-GM. Fetal liver cells from the same source were inoculated on comparative stromal layers in duplicate (means $\pm$ SD).

Fig 2. Comparison of the effect of fetal liver and bone marrow stromas on fetal liver BFU-e. The curves represent percentage recoveries of the numbers of BFU-e relative to those inoculated at time 0 (100%) and are expressed as a function of the time (weeks) of culture. Each section gives the experimental data (means $\pm$ SD) within individual experiments. △—△, cultures with fetal liver stroma; ▲—▲, cultures with marrow stroma.

adult precursor cells in long-term culture? In the last series of experiments, the capacity of fetal liver stromas to maintain marrow precursors (Table 2) in long-term cultures was examined. As compared with marrow stromas, fetal liver stromas were equally capable of maintaining marrow CFU-GM and BFU-e.

In conclusion, the favorable effect of a fetal liver stroma layer on the maintenance of erythroid progenitor cells is restricted to fetal liver BFU-e; it is not exerted on marrow BFU-e.

Morphology of the nonadherent fetal liver cells during long-term culture. The lineage-specific developments of the recharged fetal liver cells during long-term culture were assessed by cytological examination. Whereas the fetal liver is mainly erythropoietic at the time of inoculation, at 1 week of cultivation on a stroma layer, a switch to myelopoiesis was observed. After 4 to 5 weeks in vitro the nonadherent cell population was mainly composed of monocytes and macrophages. No differences were seen between cells grown on an autologous or allogeneic fetal liver stroma or those on a bone marrow stroma.

Morphology of the fetal liver stromal layers. The composition of the fetal liver stroma differed from that of the bone marrow stroma. The fetal liver fibroblasts were organized as confluent layers on the bottom of the flask. In contrast to the bone marrow cultures no patches or cobblestones were observed in cross sections of the fetal liver stroma. No fat cells appeared in the fetal liver stromal cultures as occurred in the bone marrow stromal cultures.⁶ Hematopoietic cells were scattered throughout the stroma layer. Cytochemistry of these cells did not reveal differences and confirmed the presence of macrophages, myeloblasts, and more mature myelocytic cells.

DISCUSSION

We have performed experiments to examine the specific effects of fetal liver and bone marrow stroma layers on the proliferation and differentiation of fetal and adult hemo-

Experiments 14 and 19 were done as direct comparisons with the same marrow specimen.

poietic precursors. The data presented in this study show that human fetal liver hematopoiesis in long-term culture, similar to human marrow hematopoiesis⁷⁻⁹ requires the establishment of an adherent cell layer. In direct comparative experiments it was demonstrated that the fetal liver stroma maintains fetal liver BFU-e better than the bone marrow stroma does. In contrast, marrow BFU-e, marrow CFU-GM, and fetal liver CFU-GM were supported equally well by the stroma layers of both tissues.¹⁰⁻¹² Allogeneic effects between stromas and cell inoculates were not apparent.

The hematopoietic inductive microenvironmental sites within different organs are thought to have a role in regulating hematopoiesis from the pluripotent stem cells into committed precursors.^{13,14} The microenvironments in different organs (eg, marrow, spleen, embryo liver) appear to have different specificities in determining cell lineage maturation.¹⁵ We investigated whether fetal liver stroma layers were capable of maintaining BFU-e in long-term cultures. The answer to this question is considered of interest with respect to the lack of understanding of the predominantly erythropoietic nature of the human fetal liver. Direct comparisons between the effects of fetal liver and marrow stroma layers on fetal BFU-e demonstrated a more powerful stimulative capacity of the fetal microenvironment.

BFU-e were recovered for 6 to 7 weeks when seeded on a fetal stroma, whereas, in all instances, they had disappeared before 5 weeks after their inoculation into marrow stromal cultures. Total BFU-e numbers recovered were also higher in fetal liver than in marrow stromal cultures. It is unclear which cell types in the stroma layers account for these differences. Evidence exists to suggest that macrophages and endothelial cells in human marrow stromal cultures do not influence the proliferation of marrow BFU-e.¹⁶ Marrow-derived fibroblasts appear to suppress the formation of (new) BFU-e. These cells may therefore be regarded as candidates being responsible for the discrepant effects of fetal liver and marrow stromas on BFU-e. Both in fetal liver and marrow stromal cultures BFU-e numbers dropped considerably within the first week, but in the case of fetal liver, a production of erythroid precursors was seen beyond week 2. We noted that the stimulative effect of the fetal liver microenvironment on erythroid progenitors was specific for

fetal BFU-e. When bone marrow cells were cultured on a fetal liver stroma layer, the number of adult BFU-e declined precipitously. These different values of fetal liver and marrow BFU-e on the same type of stroma are suggestive of cell dissimilarities existing between fetal liver BFU-e and marrow BFU-e and indicate alterations of the responsiveness of the erythroid precursors to stroma stimuli during human ontogeny.

Human fetal liver contains large numbers of committed myeloid progenitor cells. However, a minimal representation of granulopoiesis is apparent in histologic sections. Whether the scarce granulopoietic activity in the fetal liver organ is the result of different microenvironmental influences or instead a different responsiveness of the fetal progenitors to stimulation has not been defined. Our experiments do not reveal divergent efficiencies of fetal liver and marrow stromas as far as the production of CFU-GM is concerned. Quantitatively equivalent numbers of marrow- and fetal liver-derived CFU-GM were recovered from the fetal liver stromas (cultured for 5 to 7 weeks). In addition, fetal liver and marrow stroma layers permitted identical recoveries of CFU-GM numbers. Thus the data from these studies suggest that (a) fetal CFU-GM are susceptible to the stromal factors from both marrow and fetal liver, and (b) the fetal liver stroma layer is capable of stimulating the production of CFU-GM from adult and embryonic hematopoiesis to the same extent as bone marrow stroma layers do.

Morphological analysis revealed the predominance of myeloid cells, while erythroid cells had disappeared within 1 week of culture. As a matter of fact, it is likely that in vivo in the embryo, certain events inhibit granulopoiesis from the numerous myeloid precursors contained in the human fetal liver. A previous study¹⁰ has shown that mature granulopoietic elements from fetal liver may be detected in cultures on a bone marrow stroma layer for more than a year. This particular analysis did not include measurements of CFU-GM. We discontinued our cultures as soon as the CFU-GM had disappeared, and in our experience, at approximately week 5 of culture, the nonadherent cell population consisted mainly of macrophages, regardless of the tissue origin of the stroma layer or recharge.

We conclude from these experiments that with regard to

the regulation of erythropoiesis, both the function of the fetal liver microenvironment and the responsiveness of fetal liver progenitors (BFU-e) to stroma stimulation differ from those of the marrow stroma and marrow BFU-e. No differences were found to account for the scarcity of myelopoiesis in the fetal liver. While in vitro no active suppression of granulopoiesis exists, the rare granulopoiesis in vivo may primarily

be the consequence of the erythropoietic advantage in the embryo liver.

Factor IX_{Alabama}: A Point Mutation in a Clotting Protein Results in Hemophilia B

By Lisa M. Davis, Royal A. McGraw, Jerry L. Ware, Harold R. Roberts, and Darrel W. Stafford

Factor IX_{Alabama} is a variant factor IX molecule responsible for a clinically moderate form of hemophilia B. Twenty-five kilobases (kb) of the variant gene, including seven exons coding for the structural protein, were cloned and characterized. The restriction map and the arrangement of coding regions are identical to those of the normal gene. DNA sequence analysis of the coding regions revealed a single base-pair difference between the gene for factor IX_{Alabama}

and the normal factor IX gene. An adenine to guanine transition in the first nucleotide of exon d causes the substitution of a glycine codon (GGT) for the normal aspartic acid codon (GAT). This point mutation results in a single amino acid substitution at residue 47 of the zymogen and represents the genetic defect in factor IX_{Alabama}.
© 1987 by Grune & Stratton, Inc.

FACTOR IX is a plasma coagulation glycoprotein necessary for normal hemostasis. The factor IX zymogen has a mol wt of 56,000 daltons and can be activated by factor XIa and Ca²⁺ as well as factor VIIa-tissue factor, both of which cleave the molecule at arginyl residues 145 and 180 to release an activation peptide of ~10,000 daltons. Activated factor IX, in the presence of co-factors (Ca²⁺, phospholipid, and activated factor VIII) rapidly converts factor X to factor Xa.¹

The sequence of normal human factor IX cDNA clones and genomic clones has been previously reported.²⁻⁶ The normal gene is 35 kilobases (kb) in length and consists of eight coding regions (exons) and seven intervening sequences (introns). The full-length cDNA is 2.8 kb and includes 1.3 kb of a 3' nontranslated region. The gene has been localized to band Xq27 through Xq28 on the long arm of the X chromosome and is in close linkage with the fragile X mental retardation syndrome.⁷⁻⁹

Factor IX is absent or defective in the plasma of individuals suffering from hemophilia B (Christmas disease). This sex-linked bleeding disorder results from a variety of genetic defects in the factor IX gene.¹ Affected individuals are classified according to their plasma levels of immunologically detectable factor IX. Cross-reacting material-positive (CRM⁺) variants have essentially normal levels of factor IX antigen with reduced clotting activity. CRM-reduced (CRM^{-R}) patients have proportionately reduced levels of both antigen and clotting activity and CRM-negative (CRM⁻) individuals have virtually undetectable levels of both antigen and clotting activity.^{1,10,11}

At least eight unique CRM⁺ variants have been described.¹ The CRM⁺ variants provide a unique opportunity for understanding the complex relationship between the

protein structure of factor IX and its functional role in coagulation. When a specific mutation in one of these variants is identified and correlated with an aberrant function, an understanding of the relationship between structure and function is enhanced. One CRM⁺ variant, factor IX_{Alabama}, has been isolated from patients with moderate hemophilia B. Factor IX_{Alabama} has only 10% of the clotting activity of normal factor IX.^{12,13} In this report, we describe the genetic defect in patients with factor IX_{Alabama}. Our studies reveal a point mutation resulting in the substitution of a glycine for an aspartic acid at position 47 of the factor IX protein.

MATERIALS AND METHODS

Patients. Patients from the pedigree with factor IX_{Alabama} have been previously described.^{12,13} Factor IX was purified from the plasma of affected patients.¹⁴ After informed consent from patients, DNA was extracted from whole blood or leukocytes from the two affected patients in this kindred list.¹⁵

Factor IX_{Alabama}. Factor IX_{Alabama} was isolated from the patients' plasma as previously described.¹⁶ The mol wt and determination of γ -carboxyglutamic acid residues were performed essentially as described for factor IX_{Chapel Hill}.¹⁶ β -hydroxyaspartic acid was determined by Dr Walter Kiesel of the University of Washington, Seattle.¹⁷

Factor IX_{Alabama} genomic library. The recombinant library was constructed by ligating a size-fractionated *Eco*RI partial digest of this genomic DNA to the phage vector λ gtl- λ B.¹⁸ Conditions for sucrose gradient fractionation, ligation, and λ packaging were as described.¹⁹

Factor IX_{Alabama} clones. The library was screened for factor IX_{Alabama} clones with synthetic oligonucleotide probes or with the full-length factor IX cDNA.⁴ Oligonucleotides were end-labeled as described,¹⁹ and the full-length cDNA was radiolabeled according to a standard nick-translation protocol.²⁰ Alternatively, the full-length cDNA, subcloned into the M13 phage vector mp9, was labeled with α -³²P dATP in a reaction similar to the chain-terminating dideoxy DNA-sequencing reaction except that dideoxy nucleotides were omitted.

The factor IX_{Alabama} clones were subcloned from the λ phage vector into both pUC plasmids and M13 phage vectors to facilitate restriction analysis and DNA sequence determination. Standard procedures for construction of these subclones were followed.²¹⁻²³

DNA sequence analysis. DNA sequence analysis was done according to the method of Biggin and co-workers²⁴ or by a modification of the Sanger dideoxy chain-terminating method²⁵ using end-labeled primers.²⁶ Primer was either the universal pentadecamer (New England Biolabs) or one of the factor IX-specific synthetic oligonucleotides.⁴ The template was either an M13 single-stranded DNA or a pUC double-stranded DNA subclone.

RESULTS

The mol wt of factor IX_{Alabama} was normal. The protein has 12 γ carboxyglutamic acid residues and a β -hydroxy-

aspartic acid at position 64 (data not shown). Factor IX can be activated to the factor IXa β form of the molecule and possesses 10% of the clotting activity of normal factor IXa β . In addition, factor IX_{Alabama} is present in normal amounts, as previously demonstrated.¹²

Two factor IX genomic clones, designated LC-7 and LC-10, were isolated from the factor IX_{Alabama} library. Together they comprise 25 kb of the factor IX_{Alabama} gene. These clones include all the sequence coding for the mature structural protein and one-third of the leader peptide. The remainder of the pre-pro sequence was not determined, since the factor IX_{Alabama} protein was secreted normally, as evidenced by normal plasma antigen concentrations, and had a normal complement of γ carboxyglutamic acid residues. These findings indicated that the pre-pro portion of the gene was normal.

LC-7 was identified with an end-labeled 18-mer oligonucleotide probe, synthesized for the active serine site region of exon h. LC-10 was identified with the uniformly labeled, Klenow-extended, full-length cDNA. The identity of each clone was established initially as follows: a *Sau* 3A digest of each clone was subcloned into the *Bam*HI site of mp8 and rescreened with the original probe. The DNA sequences of positive plaques were determined and compared with the published cDNA sequences.²⁻⁴

DNA sequence analysis. Figure 1 shows the strategy used in sequencing factor IX_{Alabama}. In those cases in which sequence of only one strand was obtained, several independently derived templates were used. Because exon d contains the point substitution found to cause the functional defect of

factor IX_{Alabama} (discussed below), the DNA sequence of this region was determined in both strands from six independent M13 templates derived from different λ bacteriophage preparations.

The nucleotide sequence for ~4,600 bases of the factor IX_{Alabama} gene was determined. This included all the sequence coding for the mature structural protein, one-third of the leader peptide sequence, all the 3' nontranslated region, and some flanking intron sequence (Table 1).

The sequence throughout the mature coding region of factor IX_{Alabama} is identical to all the normal factor IX clones except at two positions. Both affect the primary amino acid sequence. One difference occurs in the third residue of the activation peptide and has been shown by us to result from a nondeleterious dimorphism that is found in both the normal and hemophilic population.⁴ The presence of either a guanine or an adenine in the first position of the codon for the third residue of the activation peptide results in either an alanine (GCT) or threonine (ACT) in this position. This corresponds to residue 148 of the zymogen. Factor IX_{Alabama} codes for a threonine in this position.

The other difference affecting the amino acid sequence is not found in any of the normal factor IX sequences and constitutes the abnormality in factor IX_{Alabama}. This difference occurs in the first nucleotide of exon d (Fig 2A). This is the second nucleotide of the triplet coding for the 47th residue of the mature protein. An adenine to guanine transition causes the substitution of a GGT codon for the normal GAT codon. This mutation results in a glycine substitution for aspartic acid at residue 47, preceding the epidermal growth-factorlike region of the protein. Figure 2B shows more clearly the DNA coding sequence of normal factor IX and factor IX_{Alabama} in this region and the corresponding translated amino acid sequence.

Two genomic factor IX sequences^{5,6} are available for comparison of intron sequences that demonstrate naturally occurring polymorphisms. Anson and colleagues⁵ reported the presence of a thymine between the cytosine and adenine that occur at 124 and 125 nucleotides 5' to exon b. This thymine is absent in both factor IX_{Alabama} and in the normal sequence, as reported by Yoshitake and co-workers.⁶ The sequence of one cDNA clone⁴ and two genomic clones^{5,6} that include the complete 3' nontranslated region have been reported. There are discrepancies between those sequences

Fig 1. Sequencing strategy. The gene is shown at top, with exons b through h enlarged in the middle. Vertical lines represent termini of restriction fragments subcloned for DNA sequence analysis: R: *Eco*RI, S: *Sau* 3A, V: *Pvu*II, T: *Sst*I, H: *Hind*III, P: *Pst*I, B: *Bgl*II, N: *Nco*I, X: *Xba*I. Each arrow represents the extent and direction of sequence obtained from individual template and primer combinations. Arrows beginning with solid boxes indicate sequence obtained from double-stranded DNA templates; simple arrows indicate sequence determined from M13 single-stranded DNA templates, using the commercial universal primer. The single arrow beginning with an open box represents sequence obtained from an M13 single-stranded DNA template, using the synthetic 18-mer as primer. The five arrows showing determination of exon d sequence were the result of two independent ligations of a 0.76-kilobase *Eco*RI/*Pvu*II fragment. Additional sequence analysis confirmed the exon d mutation in both strands (additional arrow not shown).

Table 1. Summary of Determined FIX_{Alabama} Nucleotide Sequence

Exon	Exon Length	Nucleotides 5' to Exon	Nucleotides 3' to Exon
b	164	190	188
c	25	188*	9
d	114	106	140
e	129	106	197
f	203	226	35
g	115	228	40
h	1,963†	394	54
Totals	2,713	1,250	663

*This sequence is also listed as nucleotides 3' to exon b and has not been included in the total.

†Includes 1,418 nucleotides at the 3' end that are not translated.

Fig 2. (A) Sequence analysis of factor IX_{Alabama}. Sequencing data is shown for the region of junction between intron 3 and exon d. The first nucleotide of exon d in the normal sequence (left autoradiograph) is adenine as compared with the guanine substitution in factor IX_{Alabama} (right autoradiograph). Both normal and mutant nucleotides are highlighted at the level of the asterisk. (B) The abnormal amino acid sequence in factor IX_{Alabama}. The cDNA and amino acid sequence of normal factor IX are shown at top. The cDNA and amino acid sequence of factor IX_{Alabama} are shown at bottom. Substitution of guanine for adenine in the second nucleotide of the 47th codon predicts that glycine will be substituted for the normal aspartic acid.

and the one in this report at four positions, all involving single base-pair changes. When the sequence numbers of Yoshitake and co-workers are used as a reference,⁶ the cDNA sequence and the genomic sequence show cytosine at 31,663 where factor IX_{Alabama} has thymine; similarly, both the cDNA clone and the genomic clones have adenine at position 32,056 where factor IX_{Alabama} has guanine. Factor IX_{Alabama}, however, our cDNA clone,⁴ and the normal genomic sequence⁶ are alike at two additional positions, (adenine at 32,063 and cytosine at 32,308) but different from the cDNA sequence reported by Anson and colleagues,⁵ which has guanine at both positions.

DISCUSSION

Factor IX_{Alabama} is a dysfunctional coagulation protein with a normal mol wt and a normal complement of γ carboxyglutamic acid residues,¹ suggesting that the defect is not due to gross structural alterations of the gene. Our results obtained by both restriction and DNA sequence analysis of the clones confirm that the gross structure of the factor IX gene is intact. DNA sequence analysis, however, reveals a single base-pair substitution in the coding region of factor IX_{Alabama}; an adenine to guanine transition at nucleotide 307 in the cDNA sequence⁵ (corresponds to nucleotide 10,392 in

ref 6) changes a GAT codon to a GGT codon, resulting in a glycine substitution for aspartic acid at position 47 of the protein. The substitution occurs in the amino terminal region of the "connecting peptide" in the light chain of factor IX preceding the epidermal growth factor domain. This single point substitution is the only observed structural difference between factor IX_{Alabama} and normal factor IX, suggesting that this is the genetic defect responsible for the decreased clotting activity of factor IX_{Alabama}. This substitution is sufficient to result in moderate bleeding in affected members of the factor IX_{Alabama} kindred.

DNA sequence of exon a, which codes for two-thirds of the leader peptide, was not determined. The leader peptide is believed to function in transport of the protein from the site of synthesis to its site of carboxylation in the cytoplasm of the hematocyte before secretion into the circulation. Because factor IX_{Alabama} is normally secreted and carboxylated, it is very unlikely that a defect exists in the region of exon a. Therefore absence of the sequence of exon a should not affect the conclusions drawn here regarding the defect responsible for the bleeding tendency in affected patients with factor IX_{Alabama}.

The DNA sequence of exon d was confirmed in both strands. The possibility that the substitution might be a cloning artifact is diminished by the fact that the sequence was determined from six independent templates derived from two independent preparations of the λ clone LC-10. In addition, primary amino acid sequence analysis of the isolated factor IX_{Alabama} protein confirms the presence of glycine instead of aspartic acid at position 47.²⁷

Six other nucleotide differences exist between this variant gene and previously published sequences of normal factor IX genes, but five of these do not affect the structural protein and cannot account for the defect in factor IX_{Alabama}. The sixth difference is a naturally occurring dimorphism in the third residue of the activation peptide⁴ and again cannot be responsible for the dysfunctional protein because the dimorphism is observed in both normal factor IX and factor IX_{Alabama} and in other abnormal factor IX molecules.

Together, these facts suggest that a glycine substitution for aspartic acid at residue 47 is responsible for the decreased clotting activity of the factor IX_{Alabama} molecule. Aspartic acid is a relatively large, charged residue, usually found on the surface of globular proteins, where it may interact with other proteins or cofactors. Substitution of the small, uncharged glycine may interfere with normal charge interactions occurring in this region of the protein. Alternatively, the substitution may lead to an altered conformation by virtue of the relatively flexible C-N bond of glycine. Whether the functional defect of factor IX_{Alabama} results primarily from the loss of charge interactions, an altered conformation, or some other function, remains to be established. Previous work from our laboratory has shown, however, that the binding of activated factor IX_{Alabama} with phospholipid is normal, although clotting activity is abnormal.²⁸ Thus, we assume that the functional abnormality causing the decreased clotting activity of factor IX_{Alabama} is due to the mutation at position 47 of the zymogen, although the mechanism of the defect is not yet clear and awaits further study.

ACKNOWLEDGMENT

We thank Dr John Graham for help in obtaining blood samples, Drs Roger Lundblad and Michael Griffith for useful conversations pertaining to the Alabama variant, Dr Claudia Noyes for sharing her amino acid sequence data, and Dr Walter Kiesel for performing the analysis for β -hydroxyaspartic acid. We are especially grateful to Portia Hunt for typing the manuscript.

Inhibition of Hemoglobin Production by Transferrin-Gallium

By Christopher R. Chitambar and Zorica Zivkovic

Recent clinical trials evaluating gallium nitrate as a chemotherapeutic agent have reported the development of microcytic hypochromic anemia in patients treated with this agent. Because gallium is known to bind avidly to transferrin, we examined the effect of transferrin-gallium (Tf-Ga) on hemoglobin production by Friend erythroleukemia cells in vitro. Cellular hemoglobin production, as assessed by benzidine staining, cellular hemoglobin content, and ^{59}Fe incorporation into heme, was significantly decreased following exposure of cells to Tf-Ga. Tf-Ga led to an early decrease in cellular ^{59}Fe incorporation even before changes in hemoglobin production were detected. A marked increase in cellular transferrin receptor expression

occurred following exposure of cells to Tf-Ga. Tf-Ga inhibition of hemoglobin production could be reversed and hemoglobin production could be restored to normal by addition to the media of either transferrin-iron (Tf-Fe) or iron-pyridoxal isonicotinoyl hydrazone, a compound capable of supplying iron directly to reticulocytes for heme synthesis without transferrin as a mediator. These studies provide an explanation for the development of anemia in patients treated with gallium nitrate and suggest that gallium's mechanism of chemotherapeutic action includes inhibition of cellular iron incorporation.

© 1987 by Grune & Stratton, Inc.

GALLIUM, a group IIIa metal with significant antitumor activity,^{1,2} is currently being evaluated as a cancer chemotherapeutic agent in phase II clinical trials (gallium nitrate NSC-1500). A recent clinical study reported the development of microcytic hypochromic anemia in patients treated with this agent.² Although most chemotherapeutic drugs are myelosuppressive, the resultant anemia is usually normocytic normochromic, and the development of a microcytic hypochromic anemia from chemotherapy per se is unusual.

Several studies have demonstrated that gallium shares certain characteristics with iron in that it avidly binds to transferrin³ and lactoferrin^{4,5} and can be incorporated into ferritin.⁶ The uptake of gallium-67 by cells in tissue culture is markedly enhanced by the addition of exogenous transferrin to the media^{7,8} and, although the process of gallium uptake by cells is incompletely understood, it may be mediated by the transferrin receptor.⁹ These similarities between the transport and cellular uptake of iron and gallium raise the question of whether one metal might influence the cellular handling of the other and whether such an interaction could explain the development of hypochromic microcytic anemia during treatment with gallium nitrate.

To understand the mechanism of gallium-induced anemia better, we studied the effects of transferrin-gallium (Tf-Ga) on hemoglobin production by Friend erythroleukemia cells in vitro during induction with dimethylsulfoxide (DMSO). Hemoglobin production by these cells is significantly inhibited by Tf-Ga and this decrease in hemoglobin production is

preceded by a decrease in cellular iron incorporation. Provision of adequate amounts of iron in the form of transferrin-iron (Tf-Fe) or iron-pyridoxal isonicotinoyl hydrazone (Fe-PIH)¹⁰ reverses the Tf-Ga inhibition of hemoglobin production, indicating that the anemia seen in patients during gallium nitrate treatment is due specifically to inhibition of iron incorporation into developing erythroid precursors.

MATERIALS AND METHODS

Human transferrin, ferric chloride, ferric citrate, pyridoxal hydrochloride, isonicotinic acid hydrazide, benzidine dihydrochloride, Triton X-100, and DMSO were purchased from Sigma Chemical (St Louis). Gallium nitrate was obtained from Alfa Products (Danvers, MA), and cytosine arabinoside (Ara-C) was obtained from Upjohn (Kalamazoo, MI). ^{125}I -sodium iodide and $^{59}\text{FeCl}_3$ were obtained from New England Nuclear (Boston) and Amersham (Arlington Heights, IL), respectively. Saturation of apotransferrin with ^{59}Fe and iodination of ^{59}Fe -transferrin were performed as previously described.¹¹

Tf-Fe and Tf-Ga were prepared by using modifications of previously described methods.¹² To ensure saturation of transferrin, 3 mol of metal (as ferric chloride or gallium nitrate) was added to each mol of apotransferrin (apoTf) dissolved in 20 mmol/L of acetic acid and 150 mmol/L of NaCl pH 3.5. The pH of this solution was slowly raised to 7.4 with 1 mol/L of NaHCO_3 , and the saturation of transferrin by gallium or iron was confirmed spectrophotometrically by measuring the change in absorbance at 242 nm for Tf-Ga³ and 465 nm for Tf-Fe.¹³ Stock solutions (10 mg protein/mL) of the two transferrin forms were thus prepared and used for subsequent experiments.

PIH and ferric-PIH (Fe-PIH) were prepared according to the method of Ponka and co-workers.¹⁴ Equimolar solutions of isonicotinic acid hydrazide and pyridoxal HCl in sodium acetate buffer were heated in a boiling water bath for five minutes, and the PIH precipitate that formed on cooling was washed, filtered, and dried. Fe-PIH was prepared by combining PIH with a solution of ferric citrate in a ratio of 2 moles of PIH:1 mole Fe^{3+} . The yellow PIH precipitate immediately turned red-brown when mixed with ferric citrate. The insoluble Fe-PIH complex was thoroughly washed, filtered, and dried. Fe-PIH, thus prepared, was dissolved by resuspending it in 150 mmol/L of NaCl, 10 mmol/L of KPO_4 pH 7.4 buffer, and by lowering the pH with a small amount of 0.15 mol/L of HCl. A 1-mmol/L stock solution of Fe-PIH was prepared so that the addition of Fe-PIH to the media to achieve final concentrations of 5 to 100 $\mu\text{mol/L}$ did not alter the pH of the tissue culture media.

Tissue culture. Friend erythroleukemia cells generously provided by Drs Asterios Tsiftoglou and Stephen Robinson were maintained in RPMI 1640 media containing 10% fetal calf serum

(FCS) with 200 $\mu\text{g}/\text{mL}$ of penicillin and 0.2 mg/mL of streptomycin (regular media). The original cells were further subcloned to yield a clone in which 80% to 90% of the cells demonstrated hemoglobin production after three days of exposure to 2% DMSO. The percentage of hemoglobin-producing cells was determined by benzidine staining,¹⁵ and the amount of hemoglobin produced was measured according to the method of Tsiftoglou and colleagues¹⁶ using bovine hemoglobin as a standard. In experiments examining hemoglobin production, cells were plated at 1×10^5 cells/mL in regular media or media containing 2% DMSO with various concentrations of apo-transferrin, Tf-Fe, Tf-Ga, or Ara-C. Aliquots of cells were harvested at different times following initial plating, and the effects of the different media additives on hemoglobin production were determined. In coinubation studies of hemoglobin production, cells plated in media containing 2% DMSO and Tf-Ga were also exposed to various concentrations of Tf-Fe (100 to 400 $\mu\text{g}/\text{mL}$) or Fe-PIH. In other experiments, cells were removed from media containing Tf-Ga after 24, 48, or 72 hours and were washed and resuspended at their original density in fresh media containing 2% DMSO without Tf-Ga. In converse experiments, Tf-Ga was added to the media after cells had been exposed to 2% DMSO for 24, 48, or 72 hours, and hemoglobin production was assessed by benzidine staining.

Cellular uptake of ^{59}Fe . ^{59}Fe -Tf (2.5 $\text{ng Fe}/\text{mL}$) was added to cells plated at time 0 hour in media containing 2% DMSO plus 100, 200, or 400 $\mu\text{g}/\text{mL}$ of apoTf or Tf-Ga. Following an incubation of 24 or 72 hours, cells were harvested, counted, and washed by centrifugation. The cell pellets were counted for radioactivity, and the uptake of $^{59}\text{Fe}/10^6$ cells was determined.

Intracellular distribution of ^{59}Fe following induction of hemoglobin production. Following 66 hours of cell growth in regular media or in media containing 2% DMSO with or without Tf-Ga, aliquots containing similar numbers of cells were harvested, washed with cold serum-free media and resuspended in 10 mL of serum-free media in T25- cm^2 tissue culture flasks (3×10^6 cells/mL per flask). ^{59}Fe -Tf (3.6 $\text{ng Fe}/\text{mL}$) was added to each flask, and the cells were incubated at 37 $^\circ\text{C}$ for six hours. Following this, the cells were harvested, washed with 10 mmol/L of Tris and 150 mmol/L of NaCl pH 7.4, and finally were resuspended in 1 mL of the same buffer containing 0.1% Triton X-100. The cells were disrupted by sonication and incubated overnight at 4 $^\circ\text{C}$. Cellular debris was removed by centrifugation at 10,000 g, and the cytoplasmic supernatant (containing 85% of the total ^{59}Fe radioactivity) was applied to a Sephadex G150 $1.5 \times 30\text{-cm}$ column equilibrated with the same buffer; 2-mL fractions were collected and counted for radioactivity.

^{125}I -Tf binding studies. Aliquots of cells growing in regular media, 2% DMSO media alone, or 2% DMSO media containing 200 or 400 $\mu\text{g}/\text{mL}$ of Tf-Ga were harvested at 24, 48, 72, and 96 hours following initial plating. The cells were washed twice in 10 mmol/L of KPO_4 , 150 mmol/L of NaCl pH 7.4 buffer containing 0.1% phosphate-buffered saline-bovine serum albumin (PBS-BSA), and the cell pellets were resuspended in 15 mL of PBS-BSA and incubated at 37 $^\circ\text{C}$ for 30 minutes. This 37 $^\circ\text{C}$ "preincubation" step was performed to deplete the cells of any receptor-bound transferrin and to make available all transferrin binding sites for the ^{125}I -Tf binding assay. Using immunoassays for transferrin described elsewhere,¹⁷ we have found that >95% of bound transferrin is removed with this preincubation step. Cells were then cooled to 4 $^\circ\text{C}$, washed with ice-cold PBS-BSA, and resuspended in 2 to 3 mL of the same buffer. ^{125}I -Tf binding to intact cells was performed at 4 $^\circ\text{C}$ as previously described,^{11,12} and maximal transferrin binding was calculated according to the method of Scatchard.¹⁸

RESULTS

Cell growth and cellular hemoglobin production. The addition of Tf-Ga at concentrations of 200 and 400 $\mu\text{g}/\text{mL}$ to

cells plated in media containing 2% DMSO resulted in a slight to moderate dose-dependent decrease in the rate of proliferation (Fig 1). Cells exposed to 400 $\mu\text{g}/\text{mL}$ of Tf-Ga reached a maximum density after 72 hours of incubation, with a subsequent small decrease in number by 96 hours. Cells exposed to 200 $\mu\text{g}/\text{mL}$ of Tf-Ga continued to increase in number, reaching a maximum density by 96 hours (Fig 1).

Cells exposed to 2% DMSO rapidly synthesized hemoglobin, as assessed by benzidine staining for hemoglobin-producing cells as well as by measurements of cellular hemoglobin content. In this particular subclone of Friend erythroleukemia cells, maximum benzidine positivity occurred after 72 hours of exposure to 2% DMSO, with no further increase in benzidine-positive cells at 96 hours (Fig 2). The addition of 100 to 500 $\mu\text{g}/\text{mL}$ of Tf-Fe or apoTf or 100 $\mu\text{g}/\text{mL}$ of Tf-Ga did not alter the percentage of hemoglobin-producing cells. With the addition of Tf-Ga (200 and 400 $\mu\text{g}/\text{mL}$) to the media, however, a significant decrease in hemoglobin-producing cells occurred (Fig 2). Like the control cells, cells exposed to Tf-Ga also achieved their maximum number of hemoglobin-positive cells by 72 hours, with a slight decrease in benzidine positivity thereafter. The hemoglobin content at 72 hours was $17.15 \pm 2.15 \mu\text{g}/10^7$ cells for control cells, whereas the hemoglobin content of cells exposed to 200 and 400 $\mu\text{g}/\text{mL}$ of Tf-Ga was $3.94 \pm 0.94 \mu\text{g}/10^7$ cells and $1.1 \pm 0.27 \mu\text{g}/10^7$ cells, respectively (mean $\pm$ SD of three experiments). Decreases in cellular hemoglobin production by Tf-Ga could also be demonstrated by studying the relative incorporation of ^{59}Fe into ferritin and hemoglobin during hemoglobin synthesis. Separation of subcellular components by Sephadex column chromatography revealed that ~75% of the intracellular ^{59}Fe was associated with hemoglobin in the control cells. In contrast, Tf-Ga-treated cells contained a much smaller amount of ^{59}Fe in the hemoglobin fraction, consistent with the decrease in hemoglobin production by these cells. Because maximum benzidine positivity was reached after 72 hours of incubation and

Fig 1. Effect of transferrin-gallium (Tf-Ga) on proliferation of Friend erythroleukemia cells. Friend erythroleukemia cells were plated at 1×10^5 cells/mL in media containing 2% dimethylsulfoxide (DMSO) plus different transferrin-forms. No additives, 100 $\mu\text{g}/\text{mL}$ of Tf-Ga or 100 to 500 $\mu\text{g}/\text{mL}$ of apo-transferrin (apoTf) or transferrin-iron (Tf-Fe) (●—●); Tf-Ga 200 $\mu\text{g}/\text{mL}$ (△—△); Tf-Ga 400 $\mu\text{g}/\text{mL}$ (■—■).

Cells were plated in media containing 2% dimethylsulfoxide (DMSO) plus different transferrin forms and scored for benzidine positivity on days 1 through 4. No additives, 100 µg/mL of Tf-Ga or 100 to 500 µg/mL of apotransferrin (apoTf) or transferrin-iron (Tf-Fe) (●—●); Tf-Ga 200 µg/mL (▲—▲); Tf-Ga 400 µg/mL (■—■). Values represent the mean of three experiments $\pm$ SD.

further incubation led to a progressive decrease in cell viability, subsequent studies were done during the first 72 hours of cell growth.

To determine whether the decrease in hemoglobin production that occurred in cells exposed to Tf-Ga was the result of a decrease in proliferation per se, we incubated cells in 2% DMSO media containing concentrations of Ara-C that retarded cell growth and examined the effect on hemoglobin production. Ara-C has been reported to be a weak inducer of hemoglobin synthesis in some clones of Friend erythroleukemia cells; therefore, prior to using Ara-C to retard cell growth, we determined that this drug alone did not induce hemoglobin production (data not shown). As shown in Table 1, despite a decrease in cell growth to as low as 22% of

control, cells exposed to Ara-C demonstrated benzidine positivity nearly equivalent to control. In contrast, decreases in cell growth to only 90% and 68% of control by Tf-Ga led to marked decreases in hemoglobin production. Furthermore, as shown in Table 1, when cell growth was controlled with Ara-C the addition of 100 µg/mL of Tf-Ga (a concentration that normally did not inhibit hemoglobin production) led to a marked decrease in hemoglobin production without a further decrease in cell growth. These studies suggest that the effects of Tf-Ga on cell growth and hemoglobin production are independent of each other and that the decrease in hemoglobin production following exposure of cells to higher concentrations of Tf-Ga is not directly due to decreases in the rate of cellular proliferation.

Maximum inhibition of hemoglobin production occurred when Tf-Ga was added at the time of initial plating, and the addition of Tf-Ga after cells had been growing in 2% DMSO media for 24 or 48 hours also significantly blocked further hemoglobin production. The addition of 400 µg/mL of Tf-Ga after 48 hours when >50% of the cells were benzidine positive actually resulted in a progressive decrease in the proportion of benzidine-positive cells over the subsequent 48 hours (Fig 3A). The removal of Tf-Ga from the media allowed cells to resume hemoglobin production, with the degree of recovery dependent on the time of Tf-Ga removal. Removal of Tf-Ga after the first 24 hours of incubation resulted in hemoglobin production equal to control cells, whereas removal of Tf-Ga after 48 or 72 hours led to lesser increases in hemoglobin-producing cells (Fig 3B). Cell growth and hemoglobin production beyond 96 hours could not be reliably assessed because of marked decreases in cell viability in all groups. These studies indicate that the inhibi-

Fig 3. Hemoglobin production following addition of transferrin-gallium (Tf-Ga) to media (A) or removal of Tf-Ga from media (B) at different times. A: Friend erythroleukemia cells were plated in media containing 2% dimethylsulfoxide (DMSO); 400 µg/mL of Tf-Ga was added after 24 or 48 hours of incubation (arrows). Hemoglobin production is shown (benzidine positivity) with Tf-Ga added at 24 hours (●—●) and 48 hours (▲—▲) or with control (no Tf-Ga) (■—■). A representative experiment is shown. B: Friend erythroleukemia cells were plated in media containing 2% DMSO plus 400 µg/mL of Tf-Ga. Aliquots of cells were removed at 24, 48, or 72 hours (arrows), washed free of Tf-Ga, and resuspended in fresh 2% DMSO media without Tf-Ga. Benzidine positivity was determined on days 1 through 4 following removal of Tf-Ga at 24 hours (▲—▲), 48 hours (■—■), and 72 hours (—X), or with control (Tf-Ga 400 µg/mL) (●—●). A representative experiment is shown.

tion of hemoglobin production by Tf-Ga is reversible and is dependent on the continuous presence of Tf-Ga in the media.

Cellular uptake of ^{59}Fe . Because normal hemoglobin production requires the presence of an adequate supply of iron to the erythron, we examined whether Tf-Ga might be inhibiting hemoglobin production by interfering with cellular iron utilization. ^{59}Fe uptake was determined over a 24- and 72-hour incubation period, times at which hemoglobin production was zero and maximum in the control cells. ^{59}Fe uptake by Tf-Ga-treated cells was compared with ^{59}Fe uptake by cells exposed to corresponding concentrations of apoTf. Although apoTf was used as a control in these experiments, it was undoubtedly converted to Fe-Tf by iron present in the media; hence, ^{59}Fe uptake by the control cells actually represents ^{59}Fe uptake in the presence of Fe-Tf. As shown in Table 2, radioiron incorporation into the Tf-Ga-treated cells was decreased by 57%, 58%, and 65% at 24 hours and 41%, 45%, and 57% at 72 hours for Tf-Ga concentrations of 100, 200, and 400 $\mu\text{g/mL}$, respectively.

It thus appears that following exposure of cells to Tf-Ga a decrease in cellular ^{59}Fe incorporation occurs as an early event before hemoglobin production is detectable. In addition, a decrease in cellular iron incorporation is also seen with lower concentrations of Tf-Ga (100 $\mu\text{g/mL}$) that do not significantly decrease hemoglobin production. These results suggest that the progressive inhibition of hemoglobin production seen with higher doses of Tf-Ga results from decreased availability of iron to the cells.

Coincubation studies. Because Tf-Ga appeared to decrease the cellular uptake of trace amounts of ^{59}Fe , we examined whether the addition of exogenous Tf-Fe to the 2% DMSO-Tf-Ga media could reverse the inhibitory effects of Tf-Ga on cellular hemoglobin production. As shown in Figs 4A and B, the number of hemoglobin-producing cells increased to equal control values following the addition of Tf-Fe in concentrations equivalent to the Tf-Ga present in the media. We also noted that restoration of hemoglobin production occurred only with Tf-Fe and not with apoTf, indicating that the Tf-Ga effect resulted from specific interference with cellular iron utilization.

Recent studies using reticulocytes have demonstrated that Fe-PIH can provide iron for heme synthesis without using transferrin-transferrin receptor as a mediator.¹⁰ Therefore, in an attempt to exclude Tf-Fe and Tf-Ga interactions at the

Fig 4. Effect of transferrin-iron (Tf-Fe) or iron-pyridoxal isonicotinoyl hydrazone (Fe-PIH) on inhibition of hemoglobin production by transferrin-gallium (Tf-Ga). Cells were plated in media containing 2% dimethylsulfoxide (DMSO) plus the different additives, and benzidine positivity was determined after 72 hours of culture. (A) Tf-Fe 100 or 200 $\mu\text{g/mL}$ was added to media containing 200 $\mu\text{g/mL}$ of Tf-Ga. (B) Tf-Fe 300 or 400 $\mu\text{g/mL}$ was added to media containing 400 $\mu\text{g/mL}$ of Tf-Ga. (C) Fe-PIH 10 or 30 $\mu\text{mol/L}$ was added to media containing 400 $\mu\text{g/mL}$ of Tf-Ga. Bars represent the mean of 3 to 6 experiments $\pm$ SD.

cell surface transferrin receptor level, we examined whether iron provided by Fe-PIH could overcome the inhibitory effect of Tf-Ga on cellular hemoglobin production. As shown in Fig 4C, the addition of 30 $\mu\text{mol/L}$ of Fe-PIH resulted in the return of hemoglobin-producing cells to control levels. The amount of Fe required to return hemoglobin production to normal was higher when Fe was provided as Fe-PIH (30 $\mu\text{mol/L}$) than when Fe was provided as Tf-Fe (400 $\mu\text{g/mL}$ of Tf-Fe = 10 $\mu\text{mol/L}$ Fe). This most likely reflects differences in the ability of the two Fe forms (Tf-Fe or Fe-PIH) to provide iron to the cells.

Transferrin receptor expression. ^{125}I -Transferrin binding studies were performed on cells after growth for different lengths of time in regular media, 2% DMSO media alone, or with Tf-Ga in concentrations of 200 and 400 $\mu\text{g/mL}$. Figure 5 shows that uninduced cells in regular media reached a plateau in transferrin receptor expression between 24 and 48 hours, followed by a progressive decrease in transferrin receptor expression. Induced cells (2% DMSO) displayed a progressive increase in transferrin receptor expression corresponding to their increase in hemoglobin production. In contrast, exposure of cells to 2% DMSO plus Tf-Ga led to even greater increases in transferrin receptor expression after 24, 48, and 72 hours of incubation, despite significant decreases in hemoglobin production.

DISCUSSION

We demonstrated that Tf-Ga is able to inhibit hemoglobin production in Friend erythroleukemia cells by specifically interfering with the cellular incorporation of iron. Our *in vitro* studies suggest that such a mechanism is involved *in vivo* during gallium nitrate therapy and that decreased iron incorporation into maturing erythroid precursors leads to the development of a microcytic hypochromic anemia characteristic of iron-deficient erythropoiesis. In preliminary studies, we noted that hemoglobin production by Friend erythroleukemia cells could be inhibited by the addition of gallium nitrate to tissue culture media. Under these conditions,

Table 2. Cellular Uptake of ^{59}Fe in the Presence of apoTf or Tf-Ga

Media Additive* ($\mu\text{g/mL}$)	^{59}Fe Uptake pg/ 10^6 Cells†

Fig 5. Measurement of cellular ^{125}I -Tf binding sites following cell growth in regular media, 2% dimethylsulfoxide (DMSO) media or 2% DMSO media plus transferrin-gallium (Tf-Ga). Friend erythroleukemia cells were plated at $1 \times 10^6/\text{mL}$ in the different media; after 24, 48, 72, or 96 hours, cells were harvested, receptor-bound transferrin was eluted, and assays for Tf binding were performed. Maximal Tf binding was determined. All points represent the mean of duplicate determinations in two separate experiments.

gallium rapidly binds to bovine transferrin present in the media to form Tf-Ga. A similar sequence of events most likely occurs *in vivo*: ie, gallium binds to transferrin, and the Tf-Ga complex is then able to inhibit iron uptake by erythroid precursors significantly. *In vivo*, normally only one-third of plasma transferrin is iron saturated; therefore, the remainder is free to bind gallium avidly. With the formation of increasing concentrations of Tf-Ga, iron uptake by the erythron is impaired, and significant anemia can develop.

To control the experimental conditions and the concentration of Tf-Ga in the media better, we prepared Tf-Ga and examined its effect on hemoglobin production, cellular incorporation of ^{59}Fe , and expression of transferrin receptors. We noted that Tf-Ga markedly inhibited hemoglobin production. This inhibition of hemoglobin production was independent of the mild-to-moderate decrease in cell growth seen following exposure of cells to Tf-Ga, since a decrease in hemoglobin production was not seen when cellular proliferation was markedly inhibited by Ara-C. In addition, when cell growth was controlled with Ara-C and the effects of Tf-Ga and Tf-Fe were compared, low concentrations of Tf-Ga inhibited hemoglobin synthesis without decreasing cellular proliferation. Furthermore, removal of Tf-Ga from the media led to a rapid increase in cellular hemoglobin production, indicating that a reversible noncytotoxic mechanism was involved.

Our ^{59}Fe uptake, coincubation, and transferrin receptor expression studies demonstrate that Tf-Ga inhibits cellular hemoglobin production by interfering with cellular iron incorporation. Decreases in cellular ^{59}Fe uptake were seen with concentrations of Tf-Ga that inhibited hemoglobin production and also with concentrations of Tf-Ga that did not affect hemoglobin production. These results suggest that

a decrease in cellular iron uptake is one of the first events to occur after exposure to Tf-Ga. Higher concentrations of Tf-Ga further inhibit cellular iron uptake, resulting in decreased hemoglobin production. The coincubation studies confirm that a decrease in cellular iron incorporation is responsible for the decreased hemoglobin production, since the addition of Tf-Fe or Fe-PIH to the media reversed Tf-Ga inhibition of hemoglobin production. Recent studies have demonstrated that Fe-PIH can deliver iron to reticulocytes for heme synthesis even after cell surface transferrin receptors have been removed by pronase treatment.¹⁰ Hence, the restoration of hemoglobin production by Tf-Fe or Fe-PIH in cells exposed to Tf-Ga appears to be the result of delivery of iron to the cell interior, and not to the cell surface alone.

The marked up-regulation of transferrin receptor density seen on Tf-Ga-treated cells is compatible with decreased iron incorporation into these cells. Whereas the progressive increase in transferrin receptor expression on induced cells corresponds with increased iron requirements for hemoglobin synthesis, transferrin receptor up-regulation on cells exposed to Tf-Ga reflects an attempt by these cells to overcome the block in iron incorporation. Indeed, cells that incorporated the least amount of ^{59}Fe and thus produced the least amount of hemoglobin following exposure to Tf-Ga were the ones that displayed the highest density of transferrin receptors. This increase in transferrin receptor expression in response to decreased iron availability is consistent with other studies of transferrin receptor regulation in which an up-regulation of the transferrin receptor is seen following exposure of cells to various iron chelators that limit iron availability.¹⁹⁻²¹

The mechanism whereby Tf-Ga inhibits cellular iron incorporation is currently being investigated. Our studies with human promyelocytic leukemic HL60 cells suggest that Tf-Ga-treated cells tend to release iron into the media after the initial binding and internalization steps,²² and that Tf-Ga inhibition of cellular iron uptake is not due merely to competitive binding of Tf-Ga to cell surface transferrin receptors.

Gallium appears to be a unique chemotherapeutic agent that binds to transferrin; this may result in "targeting" to certain tumors such as lymphomas, which express transferrin receptors *in vivo*²³ and are responsive to treatment with gallium nitrate.² Blockade of the transferrin receptor by an anti-transferrin receptor monoclonal antibody has been demonstrated to inhibit tumor cell growth in a nude mouse model.²⁴ Similar targeting of the Tf-Ga complex to erythroid precursors would lead to inhibition of iron incorporation into these cells and the development of a microcytic hypochromic anemia. Because the cytotoxicity of gallium appears to be due, at least in part, to inhibition of cellular iron incorporation, this interaction between iron and gallium should be kept in mind during current trials with gallium nitrate. It remains to be determined whether gallium can influence other intracellular iron-dependent processes. Tf-Ga may provide an interesting tool for examining the shunting of iron from heme, ferritin, or other intracellular compartments. Studies of the intracellular interaction between iron and gallium might "unmask" steps at which iron is required for cellular proliferation.

Characterization of the Inhibition of Tissue Factor in Serum

By George J. Broze, Jr and Joseph P. Miletich

Tissue factor (TF) is a lipoprotein cofactor that markedly enhances the proteolytic activation of factors IX and X by factor VIIa. The functional activity of TF is inhibited by serum in a time- and temperature-dependent fashion. The inhibitory effect is also dependent on the presence of calcium ions and can be reversed by calcium chelation (EDTA) and dilution, thus excluding direct proteolytic destruction of TF as the mechanism for inhibition. Using crude TF, serum immunodepleted of factor VII, and serum depleted of the vitamin K-dependent coagulation factors by BaSO₄ absorption, it is shown that TF factor inhibition requires the presence of VII(a), X(a), and an additional moiety contained in barium-absorbed serum. When each of the other required components were at saturating concentrations, half-maximal inhibition of TF occurred in reaction

mixtures containing 2% (vol/vol) of TF at a factor VII(a) concentration of 4 ng/mL (80 pmol/L), a factor X concentration of 50 ng/mL (850 pmol/L), and a concentration of barium-absorbed serum of 2.5% (vol/vol). Catalytically active factor Xa appeared to be required for the generation of optimal TF inhibition. The results are consistent with the conclusions of Hjort that barium-absorbed serum contains a moiety that inhibits the VIIa-Ca²⁺-TF complex. The role of factor X(a) in the generation of the inhibitory phenomenon remains to be elucidated. The inhibitor present in serum (plasma) may in part be produced by the liver in vivo since cultured human hepatoma cells (HepG2) secrete this inhibitory activity in vitro.

© 1987 by Grune & Stratton, Inc.

TISSUE FACTOR (TF) is a lipoprotein cofactor that triggers blood coagulation by markedly enhancing the catalytic activity of factor VIIa toward its substrates, factor X and factor IX.^{1,2} When plasma is induced to clot by the addition of small amounts of TF, the presence of factors VIII and IX appear to be required for optimum coagulation.^{3,4} The studies of Marlar and colleagues have shown that, under these circumstances (small quantities of TF), only a limited amount of activation of factor X to Xa occurs in the absence of factor VIII or IX.⁵ Although not mentioned by these authors, this implies the generation of an inhibitor in plasma that affects the activities of VII(a), TF, or the VII(a)-TF complex. Later, the same phenomena was demonstrated by Morrison and Jesty and shown to be related to the inclusion of factor X(a) in the reaction mixtures.⁶ Very recently, Sanders and co-workers confirmed the requirement for factor X(a) and found that an additional moiety in barium-absorbed plasma was also required for the generation of this inhibitory effect.⁷

These recent articles have rediscovered a phenomenon that had previously been studied extensively by several investigators.⁸⁻²² Using a specific two-stage TF assay, we show that the inhibitor most likely recognizes the TF-Ca²⁺-VII(a) complex, appears to require the presence of

catalytically active X(a), and is reversible, thus excluding a direct proteolytic effect on tissue factor.

MATERIALS AND METHODS

Materials

Affigel 10 was purchased from Bio Rad Laboratories (Richmond, CA) and bovine serum albumin (BSA), Trizma base, acrylamide, bisacrylamide, kaolin, rabbit brain cephalin, and RVV/cephalin, were bought from Sigma Chemical (St Louis). Sodium ¹²⁵I-iodide, carrier-free, was purchased from New England Nuclear (Boston) and Iodo-gen was obtained from Pierce Chemical (Rockford, IL). Diisofluorophosphate (DFP) was a product of Aldrich Chemical (Milwaukee). All other chemicals were reagent grade or better and came from Sigma or from Fisher Scientific (Pittsburgh). HepG2 cells were obtained from the American Type Culture Collection (Rockville, MD).

Serum. Blood-serum was produced by incubating blood drawn in the absence of anticoagulants in glass tubes for 2 hours at 37°C. The clot was then gently rimmed, and supernatant serum was obtained following centrifugation (4,000 g for 10 minutes). Plasma-serum was produced from pooled normal plasma (George King Biomedical, Overland Park, KS) by adding to the citrated plasma 1/10 vol of kaolin 4 g/dL in normal saline, 1/100 vol of stock rabbit brain cephalin (prepared according to the manufacturer), and 1/100 vol 2.5 mol/L of CaCl₂. After mixing, the plasma was allowed to clot for 2 hours at 37°C and was then centrifuged (4,000 g for 10 minutes). The supernatant serums were decanted, dialyzed at 4°C against 100 vol of 0.1 mol/L of NaCl, 0.05 mol/L of Tris-HCl, and 0.1% NaN₃, pH 7.5 (TS) with two changes, and stored at 4°C. Due to the dilutions associated with its preparation, we estimate that the final plasma-serum reagent had a serum concentration that was 74% that of blood-serum.

For BaSO₄ absorption, serum was dialyzed against TS with 0.01 mol/L of sodium oxalate. BaSO₄ (100 mg/mL) was then added to the serum; after mixing for 30 minutes at room temperature, the BaSO₄ was removed by centrifugation and the absorbed serum was once again dialyzed into TS buffer. This BaSO₄-absorbed serum contained <1% factor X and 1% factor VII activity of the starting serum.

Factor VII-depleted serum was produced by passing normal human serum through a column of mouse monoclonal anti-factor VII IgG linked to affigel 10 (MC 1476) as previously described.²³ Under these conditions, the factor VII-depleted serum contained ~0.9% of the factor VII activity of the starting serum.

Proteins

X coagulant protein (XCP) from Russell's viper venom (RVV), factor VII, and factor X were purified as previously described.²⁴⁻²⁶ Factor VIIa was purified from Cohn III paste. Extraction of the Cohn III paste, polyethylene glycol precipitation, and barium citrate precipitation were performed as described by Fenton and co-workers.²⁷ The factor VII(a) was then isolated from the barium citrate pellet by ammonium sulfate elution and fractionation, monoclonal immunoaffinity chromatography, and ACA 44 gel filtration as previously described.²⁵ The final preparation contained 35% single-chain factor VII and 65% two-chain factor VIIa as determined by densitometry of the Coomassie brilliant blue R-stained protein following sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions. It had a specific factor VII activity of 50 U/ μ g. For the purposes of the experiments reported here, this preparation is called VIIa.

Factor Xa was produced by incubation of purified factor X with insolubilized XCP as previously described.²⁸ DFP-treated (DIP)-factor Xa was made by incubating factor Xa with 5 mmol/L of DFP for 48 hours at 4 °C. Under these conditions, DIP-factor Xa possessed <1% the specific activity of the starting factor Xa, but still possessed 3% (wt/wt) factor X when "total" factor X activity (described below) was determined. This implied that the activation of factor X by the insolubilized XCP was incomplete (97%) and, indeed, SDS-PAGE of 25 μ g of this Xa preparation showed that it contained a trace amount of unactivated factor X.

Crude TF was prepared as previously described, and EDTA-TF was produced by extensive washing of the crude preparation with TS containing 5 mmol/L of EDTA using ultracentrifugation (105,000 g for 1 hour) and final resuspension of the pellet containing the TF activity in TS.²⁹ In a single-stage assay using normal human plasma (100 μ L), diluted EDTA-TF (100 μ L), and CaCl_2 25 mmol/L (100 μ L) a dilution of 1:1600 of this crude TF preparation gave a clotting time of 32 seconds.

Functional assays. Factor VII and factor Xa assays were performed as previously described.²⁹ Total factor X activity was determined by incubating RVV/cephalin reagent (60 μ L), the sample in TS with 1 mg/mL of BSA (TBSA) (60 μ L), and CaCl_2 25 mmol/L (60 μ L) at 37 °C. After 3 minutes, factor X-deficient plasma was added, and the time to clot formation was determined using a fibrometer (BBL, Cockeysville, MD).

A three-stage assay was developed to assay for TF inhibition (TFI). In the first stage, serum (50% vol/vol), CaCl_2 (4 mmol/L), TBSA, or other additions (eg, VIIa, X, or Xa), and EDTA-TF were incubated at room temperature unless otherwise noted. At specified times, 10- μ L samples were diluted in TBSA with 5 mmol/L of CaCl_2 or TBSA with 1 mmol/L of EDTA and assayed for TF activity using a previously described two-stage assay system.²⁵ Fifty microliters of the diluted sample (final dilution in assay 500- to 50,000-fold), 50 μ L of factor VIIa (1 μ g/mL in TBSA), 50 μ L of 25 mmol/L of CaCl_2 , and 50 μ L of factor X (10 μ g/mL in TBSA) were incubated at 37 °C. After 1 minute, 50 μ L of a mixture containing ten parts of factor X-deficient plasma and one part of rabbit brain cephalin stock reagent (prepared as described by Sigma) was added, and the time to clot formation was determined with a fibrometer (BBL). For the purposes of comparing the effect of various additions in the first stage of the assay, 100% TF activity was defined as the activity present when only TF and TBSA comprised the first stage.

SDS-PAGE was performed on 10% gels (ratio acrylamide:bis; 37.5:1) by the method of Laemmli (4% stacking gel).³⁰ Samples were boiled in the presence of 10% 2-mercaptoethanol prior to electrophoresis.

Cell culture. HepG2 cells were cultured as previously described.²³ To assess the secretion of inhibitory activity, adherent

cells were washed twice with serum-free media and then incubated in serum-free media for 3 days.

RESULTS

When crude, EDTA-washed, TF (2% vol/vol) was incubated with serum derived from blood (50% vol/vol) in the presence of CaCl_2 there was a very rapid reduction in apparent TF activity as measured in the two-stage assay (described in the Materials and Methods section) following dilution of subsamples into a buffer containing 5 mmol/L CaCl_2 . Essentially no TF inhibition could be demonstrated, however, when subsamples of the same mixtures were diluted in a buffer containing EDTA (1 mmol/L) prior to functional assay, or if EDTA (5 mmol/L) was present in the reaction mixture from the onset of the incubation (Fig 1). The inhibition occurred at a much slower rate when the reaction mixture was incubated at 4 °C v 20 °C or 37 °C (not shown).

These results suggested that the inhibitory moiety present in serum might recognize the factor VII(a)-TF complex, which requires the presence of Ca^{2+} , and disassociates following chelation with EDTA.³¹ The reversibility of TFI with calcium chelation also meant that the inhibition was not due to enzymatic destruction of TF itself.

Effect of VII(a) Concentrations on TF Inhibition

To confirm that factor VII(a) was required for the generation of this apparent TFI, an additional experiment was performed. Plasma-serum (50% vol/vol), depleted of factor VII(a) by affinity chromatography (residual VII activity 0.9%), was tested for its ability to inhibit TF (2% vol/vol) in

Fig 1. Inhibition of tissue factor (TF) in serum. A mixture containing 50% (vol/vol) blood serum, 2% (vol/vol) TF and 4 mmol/L of CaCl_2 was incubated at room temperature. Samples were removed at indicated times, diluted into buffer containing 5 mmol/L of CaCl_2 and assayed for TF activity (●—●). At 30 minutes, a sample was also diluted in buffer containing 1 mmol/L of EDTA, and the apparent TF activity determined at specific times following dilution (○—○). The TF activity remaining in an identical reaction mixture containing 5 mmol/L of EDTA rather than 4 mmol/L of CaCl_2 from the onset was also determined (dilutions into buffer containing CaCl_2) (Δ—Δ).

the presence of varying amounts of exogenous VIIa. Figure 2 shows that with increasing concentrations of VIIa, increasing TFI occurred. Furthermore, 50% inhibition of the TF occurred at concentrations of added VIIa between 1.25 and 2.5 ng/mL. Taking into account the residual VII(a) in the depleted serum (~4 ng/mL), which was 50% vol/vol of the sample, this corresponds to a total concentration of VII(a) in the incubation mixtures of 3.25 to 4.45 ng/mL. These VII(a) concentrations are remarkably similar to those required to half-saturate TF-binding sites on monocytes in a purified system.³¹ Direct comparison between the kinetic data derived from the purified system and the results in the complex mixtures containing serum and a crude brain homogenate as a source of TF used must, however, be made with caution. It is clear from Fig 2 that the TFI appears to reach a plateau by ~30 minutes of incubation.

Effect of X Concentrations on TFI

To assess the requirement of factor X for TFI noted previously by Morrison and Jesty,⁶ and Sanders and co-workers,⁷ plasma-serum was BaSO₄ absorbed. Reaction mixtures containing BaSO₄-absorbed plasma-serum (50% vol/vol), added VIIa (final concentration 100 ng/mL), and varying concentrations of X were incubated for 30 minutes, and the degree of TFI was determined. Figure 3 shows the relationship between TFI and concentrations of exogenous, added X in the reaction mixtures. By extrapolating the curve to 0 TFI, we estimate that the barium-absorbed serum contributed an additional 12.5 ng/mL of X to the reaction mixtures, which agrees well with the results of the functional assays of the serum before and after BaSO₄ absorption. The insert to Fig 3 shows the double-reciprocal plot of 1/TFI v 1/total X (X remaining in the barium-absorbed serum plus exogenously added X). Fifty percent inhibition occurred at a total X concentration of 50 ng/mL in the reaction mixture.

Fig 2. Effect of factor VIIa on tissue factor (TF) inhibition. Mixtures containing 50% (vol/vol) plasma-serum immunodepleted of factor VII(a), 2% (vol/vol) TF, 4 mmol/L of CaCl₂, and various concentrations of exogenously added factor VIIa were incubated at room temperature. Remaining TF activity was determined: no added factor VIIa (●—●); 1.25 ng/mL (◇—◇); 2.5 ng/mL (▲—▲); 5 ng/mL (△—△); 10 ng/mL (■—■); 50 ng/mL (○—○); and 100 ng/mL (●—●) of factor VIIa. Plasma-serum prior to immunodepletion of factor VII (a) (□—□).

Fig 3. Effect of factor X on tissue factor inhibition (TFI). Mixtures containing 50% (vol/vol) BaSO₄-absorbed plasma-serum, 2% (vol/vol) TF, 100 ng/mL of factor VIIa, and various concentrations of exogenously added factor X were incubated at room temperature for 30 minutes, and the degree of TFI was determined. Inset: y axis, 1/TFI; x axis, 1/total factor X concentration in the reaction mixture. Total factor X is the sum of the amount of exogenous factor X added plus the estimated factor X remaining in the BaSO₄-absorbed serum.

Effect of Serum Concentrations on TFI

To confirm that TFI in serum required not only VII(a) and X(a) but an additional moiety present in barium-absorbed serum, the experiment depicted in Fig 4 was performed. The degree of TFI in mixtures containing VIIa and X (100 ng/mL and 1 μg/mL, respectively), 2% (vol/vol) TF, and varying concentrations of BaSO₄-absorbed plasma-serum was determined. Under these conditions, 50% TFI occurred at a concentration of barium-absorbed serum of 2.5% (vol/vol).

Requirement for Catalytically Active Xa

Reaction mixtures containing 2% (vol/vol) TF and 50% (vol/vol) plasma-serum were prepared containing X, Xa, or

Fig 4. Effect of serum concentration on tissue factor inhibition (TFI). Mixtures (total volume 100 μL) containing 2% (vol/vol) tissue factor, 100 ng/mL of factor VIIa, 1 μg/mL of factor X, 4 mmol/L of CaCl₂, and varying amounts of BaSO₄-absorbed plasma-serum were incubated for 30 minutes at room temperature and the degree of TFI was determined. Inset: y axis, 1/TFI; x axis, 1/serum (μL).

DIP-Xa (250 ng/mL) in the presence or absence of VIIa (100 ng/mL). The extent of TFI was determined following 30 minutes of incubation and is presented in Table 1. It is evident that the addition of both VIIa and X or Xa was required to generate optimum TFI, whereas Xa alone was insufficient (+VIIa v -VIIa columns, Table 1). Furthermore, in mixtures containing additional VIIa, DIP-factor Xa was less effective than X(a) (22.1% v 89.1% TFI) with the degree of TFI detected in the sample containing DIP-factor Xa probably related to contaminating factor X (3% wt/wt) in the preparation (19.2% TFI).

Production of TF Inhibitory Activity by Human Hepatoma Cells

It has been suggested that the inhibitor of the VII-TF complex may be a lipoprotein,^{7,32} and we noted that the serum inhibitory activity is found in the total lipoprotein fraction following centrifugation of serum at a density of 1.21 g/ml (data not shown).³³ In view of this, it seemed likely that the liver might be a potential source of this inhibitory agent. Therefore, the serum-free conditioned media from human hepatoma cells (HepG2) cultured in vitro was tested for TF inhibitory activity in the three-stage assay described in the Materials and Methods section. The results (Fig 5) indeed showed substantial apparent inhibitory activity in the conditioned media that increased progressively over the time period examined.

DISCUSSION

The apparent inhibition of tissue thromboplastin (TF) by serum was studied extensively by early investigators.⁸⁻²² Perhaps this effect was most dramatically demonstrated by experiments showing that prior incubation of tissue thromboplastin with serum prevented its mortal effect when infused into mice.¹⁰⁻¹⁵ Additional experiments demonstrated that the inhibition of thromboplastin was calcium dependent, reversible, and exhaustible.¹⁵⁻¹⁹ These results were confirmed and extended in elegant studies performed by Hjort.²⁰ He concluded that barium-absorbed serum contained an inhibitor that recognized "convertin" [TF-Ca²⁺-VII(a)], but had no effect on "proconvertin" [VII(a)] or thromboplastin (TF). Because Hjort's proconvertin reagent also contained factor X(a), he was unable to discern the more recently described requirement of X(A) for the inhibition.^{6,7}

Table 1. Effect of X, Xa, and DIP-Xa on Tissue Factor Inhibition in BaSO₄-Absorbed Plasma-Serum

X Preparation Added	Tissue Factor Inhibition (%)*	
	+ VIIa†	- VIIa
X (250 ng/mL)‡	89.0	19.6
Xa (250 ng/mL)	89.1	22.5
DIP-Xa (250 ng/mL)	22.1	19.6
X (7.5 ng/mL)	19.2	19.6
None	13.5	13.4

DIP = Xa, diisofluorophosphate-treated factor Xa.

‡Final concentration of X preparation in incubation mixture.

Fig 5. Secretion of inhibitory activity by HepG2 cells in vitro. HepG2 cells were grown to confluence in media containing 10% fetal calf serum. The serum-containing media was then removed, and the cells were washed twice with serum-free media before subsequent incubation in serum-free media. Samples of the serum-free-conditioned media were removed on day 1 (○—○), 2 (▲—▲), and 3 (△—△), and tested for the ability to inhibit tissue factor (TF) in mixtures containing 50% (vol/vol) conditioned media, 2% (vol/vol) TF, 100 ng/mL of factor VIIa, 1 µg/mL of factor X, and 4 mmol/L of CaCl₂ incubated at room temperature. Serum-free media control (●—●).

Investigating the activation of ³H-labeled X or IX in specifically depleted plasmas on the addition of TF, Morrison and Jesty confirmed previous work by Marlar and co-workers showing that the extent of activation of X (and IX) was incomplete.^{5,6} The inclusion of X or Xa in their reaction mixtures appeared to be associated with the ultimate plateau in X and IX activation. They hypothesized that Xa might proteolytically destroy the VII(a) present since, in their hands, the addition of further TF did not cause further activation of X. Sanders and colleagues, who also studied the activation of X and IX in plasma using the release of ³H activation peptides, found that the addition of further TF to a reaction mixture in which factor X activation had plateaued produced further factor X activation, implying that the apparent inhibition of factor X activation was not due to proteolytic destruction of all the VII(a) in plasma.⁷ They suggested instead, that the inhibitory effect was related to the destruction of TF.

Our results, however, in agreement with those of Hjort, suggest that the inhibitory factor present in barium-absorbed serum reacts with the factor VII(a)-Ca²⁺-TF complex and does not destroy TF per se since TF functional activity can be recovered following chelation of Ca²⁺ and dilution.³¹ Rao and colleagues, using different methods, recently reached a similar conclusion.³⁴ Furthermore, our studies make it unlikely that the inhibition of factor X activation by VIIa-TF is due to proteolytic destruction of VIIa since it persisted following dilution and the addition of more VIIa (steps used to

measure TF activity here). In another experiment (not shown), ^{125}I -radiolabeled VII (4 ng/mL) was incubated with 50% (vol/vol) immunodepleted factor VII-deficient plasma-serum, and 20% (vol/vol) TF. Samples were removed following incubation of the mixture at room temperature, subjected to SDS-PAGE under reducing conditions, and autoradiographed. Under these conditions, cleavage of ^{125}I -VII to two-chain factor VIIa was observed, but no additional proteolysis of VII could be detected.

To produce optimal TF inhibition in BaSO_4 -adsorbed serum, both VIIa and X(a) were required. Thus, the role of VIIa in the mixtures was not simply the activation of X since Xa alone was insufficient. Furthermore, the function of Xa was not simply the activation of VII since the addition of VIIa (our preparation contained 65% two-chain, activated VII) to BaSO_4 -adsorbed serum was also insufficient to produce maximal TF inhibition. Although the indirect evidence presented here strongly supports the supposition that the inhibitor recognizes the VII(a)- Ca^{2+} -TF complex, thus explaining the requirement for VII(a), the role of X(a) remains to be elucidated. The results depicted in Table 1 suggest that catalytically active Xa is required for some step in the generation of the inhibitory activity in serum and, in additional studies (not shown), we found that complexes of Xa-antithrombin III (or Xa-soybean trypsin inhibitor), will not suffice. With this in mind, and because serum contains inhibitors to Xa, it appears likely that the concentration of X(a) required for 50% TF inhibition as shown in Fig 3 (50 ng/mL) is probably an overestimate. Whether a stoichiomet-

ric complex of VII(a)-TF-Xa might be involved in the inhibitory process, however, will require isolation of the factor present in barium-adsorbed serum (plasma) to allow experiments in purified systems.

Carson has reported that high-density lipoproteins (HDLs) inhibit the activation of factor X by factor VIIa and TF.³² We found, however, that HDL isolated using polyanion precipitation and density centrifugation³⁵ did not affect TF activity when measured in the assay system described here. Thus, the inhibition noted by Carson may involve a separate mechanism from that of the inhibitor of VIIa-TF we are studying. Kondo and Kisiel have recently described the isolation of a lipoprotein that inhibits factor VIIa-TF activation of factor X.³⁶ This moiety copurified with factor X through a number of chromatography steps and was found to inhibit the activation of X by the VIIa-TF complex in a noncompetitive fashion, suggesting to them that its mechanism of action involves the sequestration of either VII(a) or X. The relationship between this lipoprotein and the serum factor associated with apparent TFI that is the subject of this report is unclear. Moreover, although the characteristics of the latter inhibitor are compatible with noncompetitive inhibition, our results appear to make the sequestration of VIIa or X per se an unlikely mechanism of its action.

ACKNOWLEDGMENT

We would like to thank Darryl Higuchi and Melissa Pigg for excellent technical assistance and Betty Greene for preparing this manuscript.

Association of Red Cell Spherocytosis With Deletion of the Short Arm of Chromosome 8

By Robert R. Chilcote, Michelle M. Le Beau, Carlton Dampier, Eugene Pergament, Yury Verlinsky, Narla Mohandas, Henri Frischer, and Janet D. Rowley

Congenital spherocytic anemia is a common disorder, but in most cases the nature of the underlying membrane lesion is unknown and the genetic defect has not yet been unequivocally mapped to a chromosome. We studied two dysmorphic siblings with neurologic findings and hemolytic anemia. Clinical and laboratory findings in these two siblings were consistent with the diagnosis of congenital spherocytosis whereas both parents and two unaffected

siblings were normal. The two affected children had an abnormal chromosomal complement as a result of a deletion of the short arm of chromosome 8 [(46,XX,del(8)(p11.1p21.1)]. These results suggest that a gene whose deletion results in a congenital spherocytic anemia phenotype resides on this region on the short arm of chromosome 8.

© 1987 by Grune & Stratton, Inc.

CONGENITAL or heritable spherocytosis (HS) is a hemolytic anemia of variable severity, ordinarily inherited in an autosomal dominant fashion and alleviated by splenectomy. Although HS is associated with RBC membrane loss that results in characteristic findings in osmotic fragility studies, in the majority of cases studied, no consistent molecular membrane defect has been identified and no study has unambiguously assigned the defective gene(s) to a chromosome. Kimberling and associates^{1,2} described a family with both HS and a balanced translocation between chromosomes 8 and 12, whereas Bass and associates³ described another family with HS and a translocation between chromosomes 3 and 8, suggesting that a functional alteration in a gene on chromosome 8 would result in spherocytosis. We report two sisters with typical spherocytosis, dysmorphology, and an interstitial deletion of the short arm (p) of chromosome 8.

MATERIALS AND METHODS

Case reports. The family was first brought to medical attention because of anemia in C.H. (Table 1). Born in 1978, this child was small (birth weight 2,500 g; length 38 cm), had hyperbilirubinemia

in the second day of life and gained weight slowly. In the first months of life, intermittent splenomegaly, anemia, reticulocytosis, and microspherocytes in the peripheral smear were noticed. When the child was aged 6 months, psychomotor retardation, unusual facies, and nystagmus became evident and tonic-clonic seizures occurred. The results of osmotic fragility studies of RBCs before and after 24-hour incubation were characteristic of spherocytosis. The patient required several transfusions following respiratory infections in the first years of life. After splenectomy was performed when she was aged 4 years, her hemoglobin levels and reticulocyte counts have been normal and transfusions have not been necessary. However, microspherocytes persist on the peripheral smear, and osmotic fragility studies of both fresh and incubated erythrocytes continue to show increased fragility.

The second child, born in 1980, was also small at birth (birth weight 2,700 g; length 41 cm); she developed similar dysmorphic features with nystagmus, psychomotor retardation, and intermittent splenomegaly. Hematologic studies revealed that she also has spherocytosis. Anemia was not as severe as in the first child, and no transfusions have been required.

Both children attend schools for the educationally handicapped, have grown more slowly than their peers, and have a slight mongoloid slant, a pit located anterior to one ear, and micrognathia. The parents are unrelated and of normal appearance (mother's height 65 inches; father's height 79 inches) and are college graduates. There was no family history of congenital anomalies, anemia, jaundice, gall bladder disease, or splenectomy. On two occasions, the complete blood counts, blood films, serum bilirubins, haptoglobin levels, and osmotic fragility studies (before and after 24-hour incubation at 37 °C) on both parents were normal.

A third female child born in 1983 was normal (birth weight 3,540 g; length 45 cm) and by 3 years of age had not developed dysmorphic features, neurologic problems, or evidence of spherocytic anemia. A fourth child was born in 1986 and at 9 months of age shows normal development, is not dysmorphic, and has normal blood counts.

Laboratory studies. Using previously described techniques, RBC ektacytometric studies⁴ were performed, and carbonic anhydrase⁵ and glutathione reductase (GSSG-R) levels⁶ were measured on the two affected children and both parents. Plasma factor VII levels were measured using factor-deficient plasma (Dade Diagnostics). Peripheral blood RBCs were separated by density.⁷ Membrane proteins from RBC ghosts prepared by hypotonic lysis were separated using sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) as described⁸ (except 0.1% SDS gel and buffers were used to enhance resolution of band 4.1) and the two-dimensional gel technique of O'Farrell.⁹ One-dimensional gels were stained with Coomassie blue and scanned with a Hoefer GS300 scanning densitometer to estimate the area under each peak. Relevant protein bands were also excised and, after eluting with 80% methanol at 95 °C, the Coomassie blue stain in each band was quantitated at 595 nm in a spectrophotometer.¹⁰ RBC phospholipids

Table 1. Hematologic Values for the Two Patients

Variable	C.H.*		B.H.
	Before Splenectomy	After Splenectomy	
Age (yr)	4	6	4
Hemoglobin (g/dL)	9.2	15.2	10.2
Reticulocytes (%)	20	1.4	8.8
MCHC (g/dL)	35.0	35.9	34.6
Microspherocytes (0-4+)	2+	4+	2+

*This patient had hyperbilirubinemia in the newborn period and, before splenectomy, four severe anemic episodes associated with splenomegaly and requiring transfusions. Hematologic values were obtained during stable periods with no recent transfusions. Two normal-appearing siblings have normal hematologic studies.

were assayed using ammonium ferrothiocyanate¹¹ and silica gel (Fischer Silicon Gel G) thin-layer chromatography.¹² Trypsin-Giemsa-banded chromosome studies were performed on phytohemagglutinin-stimulated peripheral blood lymphocytes on two occasions on each family member and on cultures established from skin biopsies of the parents. Multiple blood group and HLA markers were determined on both parents and the two older children.

RESULTS

Hematologic studies. The results of osmotic fragility studies of unincubated RBCs from one affected child (C.H.), are shown in Fig 1. Density centrifugation of fresh peripheral blood enriched the lower or denser, presumably older layers (as judged by the absence of reticulocytes), for spherocytes. Also shown in Fig 1 are the results of osmotic fragility studies obtained at the time of this child's splenectomy. RBCs taken from the splenic pulp and splenic vein had a higher propor-

tion of osmotically fragile RBCs than did the peripheral blood, consistent with splenic "conditioning."^{13,14}

Genetic studies. Metaphase cells from both affected children had an interstitial deletion of the short arm of chromosome 8 extending from band p11.1 to p21.1 (Fig 2): [46,XX,del(8)(p11.1p21.1)]. Peripheral blood lymphocytes from one unaffected sibling and both lymphocyte and skin fibroblast cultures from the parents had normal chromosomal complements.

RBC GSSG-R levels in the affected children were slightly lower than those of either parent, one unaffected sibling, or controls (C.H.: 8.6, 6.3; B.H.: 9.0, 11.2; unaffected sibling: 13.7; mother: 12.0, 15.2; father: 12.4; and nine controls: 13.2 ± 2.4 mmol/min/g Hb SD). Carbonic anhydrase I and II and plasma factor VII levels were not reduced. Blood group and lymphocyte HLA studies gave no evidence of nonpaternity.

Membrane studies. Ektacytometric studies of peripheral blood taken from both parents and the affected children were normal. These findings are consistent with the results noted in patients with classical hereditary spherocytosis in whom no specific skeletal protein defect can yet be identified.⁴

SDS-polyacrylamide gels of RBC ghosts isolated from a normal control and the family members are illustrated in Fig 3. Spectrin (both α and β), actin, band 4.1, and other bands delineated by this technique were present; results were confirmed by two-dimensional gel analysis. Table 2 shows that the ratios of spectrin, band 4.1, and band 4.2 to band 3 for each of the affected children, both parents, and controls were similar. The membrane phospholipids, sphingomyelin, phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine were present in normal proportions.

Fig 1. Osmotic fragility studies of C.H.'s peripheral RBCs (separated by density) and splenic RBCs. The results of studies of peripheral blood taken during a routine visit and separated by RBC density (centrifuged at 30 °C for 60 minutes at 27,000 g (ref. 7) show that the least dense fraction with the highest proportion of reticulocytes from the top of the gradient was, as judged by osmotic fragility, the least severely damaged, whereas the denser layers (middle and bottom of the gradient, no reticulocytes) had a higher proportion of spherocytic cells (tail of osmotically fragile cells), suggesting that the patient's RBCs sphered with age. Studies of peripheral blood from a normal control (right-hand curves) showed no shift in osmotic fragility between top and bottom RBC layers. At the time of splenectomy, samples obtained from the splenic pulp and splenic vein contained the highest proportion of spherocytes, suggesting that the spleen was damaging RBCs in transit.

Fig 2. Interstitial deletion of chromosome 8. A: Schematic diagram of the banding pattern of the normal (left) and deleted (right) chromosome 8. The deleted segment is identified by arrows on the normal homologue. B through E: Partial karyotypes of family members illustrating chromosome 8 homologues from trypsin-Giemsa-banded metaphase cells derived from phytohemagglutinin-stimulated peripheral blood lymphocytes. B, father; C, mother; D, patient C.H.; E, patient B.H. D and E: The deleted chromosome is shown on the right of each pair of homologues (arrows).

DISCUSSION

The association of congenital spherocytic anemia in these two siblings with an interstitial deletion of the short arm of chromosome 8 and the absence of these findings in other family members with normal chromosomal complements strongly suggests that the loss of this chromosomal segment resulted in the RBC membrane abnormality. The clinical

Table 2. Comparison of Ratios of Spectrin, Band 4.1, and Band 4.2 to Band 3

Sample	Spectrin:Band 3	Band 4.1:Band 3	Band 4.2:Band 3
Father	1.06 ± 0.08	0.24 ± 0.01	0.14 ± 0.02
Mother	1.05 ± 0.04	0.23 ± 0.04	0.14 ± 0.02

C.H.	1.06 ± 0.06	0.25 ± 0.02	0.14 ± 0.02
Control	1.08 ± 0.06	0.25 ± 0.02	0.15 ± 0.02

All results are means ± SD (n = 7). Results were determined by dye elution of Coomassie blue stain of 3.5% to 7.5% gradient sodium dodecyl sulfate polyacrylamide gels.

course, hematologic findings, osmotic fragility studies, the role of the spleen in damaging RBCs, membrane loss with cell age, and ektacytometric measures of RBC structural stability in these two patients are compatible with previous descriptions of patients with congenital spherocytic anemias such as HS.^{4,12,14}

Kimberling and associates described a family with spherocytosis and a balanced translocation between chromosomes 8 and 12 [t(8;12)(p11;p13)],^{1,2} whereas Bass and associates³ described another family with spherocytosis and a translocation between chromosomes 3 and 8 [t(3;8)(p21;p11)]. These data, along with our observations of an interstitial deletion involving bands p11.1 and p21.1, suggest that a functional alteration in a gene on the short arm of chromosome 8, at band p11, is associated with spherocytosis.

GSSG-R levels were slightly reduced in the two affected children relative to their parents and the unaffected sibling but did not approach half-normal values expected from GSSG-R gene dosage studies in patients trisomic for this region of chromosome 8.¹⁵ These results are ambiguous and do not confirm or deny the cytogenetic findings, which indicate that the deletion extends to 8p21, the region to which the GSSG-R gene has been assigned.¹⁶ It is unlikely that the moderate reduction in GSSG-R activity would cause hemolysis and, in a previous study of a kindred with both HS and GSSG-R deficiency, the two genes segregated independently and family members who had GSSG-R deficiency alone were asymptomatic.¹⁷ Levels of carbonic anhydrase II and factor VII, genes with structural or control loci assigned to chromosome 8,¹⁸ were not reduced, but the deletion observed in our patients probably involved a number of other genes, resulting in dysmorphology and the neurologic findings.

The pattern of inheritance in this family is unusual in that two siblings were affected whereas the parents and a third sibling were chromosomally normal. Cytogenetic analysis on a fourth sibling has not yet been performed, but the child has a normal physical exam and hemoglobin values. Studies of blood groups and HLA antigens in this family were consistent with the presumed paternity. Although other possible mechanisms may explain our observations, the most likely explanation is that one parent is mosaic for this abnormality.

It is likely that congenital spherocytic anemias are a heterogeneous group of disorders but, other than a deficiency of α and β spectrin described in a small number of patients,¹⁹

Fig 3. Sodium dodecyl sulfate 3.5% to 7.5% gradient polyacrylamide gel electrophoresis of RBC ghosts. Gels were stained with Coomassie blue. Shown are the gels of both parents (lanes 1 and 2), affected patients C.H. and B.H. (lanes 3 and 4), and a normal control (lane 5). There were no major differences in membrane protein composition between the affected children, parents, and control.

Table 1. Hematologic Values for the Two Patients

Variable	C.H.*		B.H.

Age (yr)	4	6	4
Hemoglobin (g/dL)	9.2	15.2	10.2
Reticulocytes (%)	20	1.4	8.8
MCHC (g/dL)	35.0	35.9	34.6
Microspherocytes (0-4+)	2+	4+	2+

*This patient had hyperbilirubinemia in the newborn period and, before splenectomy, four severe anemic episodes associated with splenomegaly and requiring transfusions. Hematologic values were obtained during stable periods with no recent transfusions. Two normal-appearing siblings have normal hematologic studies.

were assayed using ammonium ferrothiocyanate¹¹ and silica gel (Fischer Silicon Gel G) thin-layer chromatography.¹² Trypsin-Giemsa-banded chromosome studies were performed on phytohemagglutinin-stimulated peripheral blood lymphocytes on two occasions on each family member and on cultures established from skin biopsies of the parents. Multiple blood group and HLA markers were determined on both parents and the two older children.

RESULTS

Hematologic studies. The results of osmotic fragility studies of unincubated RBCs from one affected child (C.H.), are shown in Fig 1. Density centrifugation of fresh peripheral blood enriched the lower or denser, presumably older layers (as judged by the absence of reticulocytes), for spherocytes. Also shown in Fig 1 are the results of osmotic fragility studies obtained at the time of this child's splenectomy. RBCs taken from the splenic pulp and splenic vein had a higher propor-

tion of osmotically fragile RBCs than did the peripheral blood, consistent with splenic "conditioning."^{13,14}

Genetic studies. Metaphase cells from both affected children had an interstitial deletion of the short arm of chromosome 8 extending from band p11.1 to p21.1 (Fig 2): [46,XX,del(8)(p11.1p21.1)]. Peripheral blood lymphocytes from one unaffected sibling and both lymphocyte and skin fibroblast cultures from the parents had normal chromosomal complements.

RBC GSSG-R levels in the affected children were slightly lower than those of either parent, one unaffected sibling, or controls (C.H.: 8.6, 6.3; B.H.: 9.0, 11.2; unaffected sibling: 13.7; mother: 12.0, 15.2; father: 12.4; and nine controls: 13.2 ± 2.4 mmol/min/g Hb SD). Carbonic anhydrase I and II and plasma factor VII levels were not reduced. Blood group and lymphocyte HLA studies gave no evidence of nonpaternity.

Membrane studies. Ektacytometric studies of peripheral blood taken from both parents and the affected children were normal. These findings are consistent with the results noted in patients with classical hereditary spherocytosis in whom no specific skeletal protein defect can yet be identified.⁴

SDS-polyacrylamide gels of RBC ghosts isolated from a normal control and the family members are illustrated in Fig 3. Spectrin (both α and β), actin, band 4.1, and other bands delineated by this technique were present; results were confirmed by two-dimensional gel analysis. Table 2 shows that the ratios of spectrin, band 4.1, and band 4.2 to band 3 for each of the affected children, both parents, and controls were similar. The membrane phospholipids, sphingomyelin, phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine were present in normal proportions.

Fig 1. Osmotic fragility studies of C.H.'s peripheral RBCs (separated by density) and splenic RBCs. The results of studies of peripheral blood taken during a routine visit and separated by RBC density (centrifuged at 30 °C for 60 minutes at 27,000 g (ref. 7) show that the least dense fraction with the highest proportion of reticulocytes from the top of the gradient was, as judged by osmotic fragility, the least severely damaged, whereas the denser layers (middle and bottom of the gradient, no reticulocytes) had a higher proportion of spherocytic cells (tail of osmotically fragile cells), suggesting that the patient's RBCs sphered with age. Studies of peripheral blood from a normal control (right-hand curves) showed no shift in osmotic fragility between top and bottom RBC layers. At the time of splenectomy, samples obtained from the splenic pulp and splenic vein contained the highest proportion of spherocytes, suggesting that the spleen was damaging RBCs in transit.

Fig 2. Interstitial deletion of chromosome 8. A: Schematic diagram of the banding pattern of the normal (left) and deleted (right) chromosome 8. The deleted segment is identified by arrows on the normal homologue. B through E: Partial karyotypes of family members illustrating chromosome 8 homologues from trypsin-Giemsa-banded metaphase cells derived from phytohemagglutinin-stimulated peripheral blood lymphocytes. B, father; C, mother; D, patient C.H.; E, patient B.H. D and E: The deleted chromosome is shown on the right of each pair of homologues (arrows).

DISCUSSION

The association of congenital spherocytic anemia in these two siblings with an interstitial deletion of the short arm of chromosome 8 and the absence of these findings in other family members with normal chromosomal complements strongly suggests that the loss of this chromosomal segment resulted in the RBC membrane abnormality. The clinical

Table 2. Comparison of Ratios of Spectrin, Band 4.1, and Band 4.2 to Band 3

Sample	Spectrin:Band 3	Band 4.1:Band 3	Band 4.2:Band 3
Father	1.06 ± 0.08	0.24 ± 0.01	0.14 ± 0.02
Mother	1.05 ± 0.04	0.23 ± 0.04	0.14 ± 0.02
B.H.	1.06 ± 0.05	0.23 ± 0.03	0.14 ± 0.02
C.H.	1.06 ± 0.06	0.25 ± 0.02	0.14 ± 0.02
Control	1.08 ± 0.06	0.25 ± 0.02	0.15 ± 0.02

All results are means ± SD (n = 7). Results were determined by dye elution of Coomassie blue stain of 3.5% to 7.5% gradient sodium dodecyl sulfate polyacrylamide gels.

course, hematologic findings, osmotic fragility studies, the role of the spleen in damaging RBCs, membrane loss with cell age, and ektacytometric measures of RBC structural stability in these two patients are compatible with previous descriptions of patients with congenital spherocytic anemias such as HS.^{4,12,14}

Kimberling and associates described a family with spherocytosis and a balanced translocation between chromosomes 8 and 12 [t(8;12)(p11;p13)],^{1,2} whereas Bass and associates³ described another family with spherocytosis and a translocation between chromosomes 3 and 8 [t(3;8)(p21;p11)]. These data, along with our observations of an interstitial deletion involving bands p11.1 and p21.1, suggest that a functional alteration in a gene on the short arm of chromosome 8, at band p11, is associated with spherocytosis.

GSSG-R levels were slightly reduced in the two affected children relative to their parents and the unaffected sibling but did not approach half-normal values expected from GSSG-R gene dosage studies in patients trisomic for this region of chromosome 8.¹⁵ These results are ambiguous and do not confirm or deny the cytogenetic findings, which indicate that the deletion extends to 8p21, the region to which the GSSG-R gene has been assigned.¹⁶ It is unlikely that the moderate reduction in GSSG-R activity would cause hemolysis and, in a previous study of a kindred with both HS and GSSG-R deficiency, the two genes segregated independently and family members who had GSSG-R deficiency alone were asymptomatic.¹⁷ Levels of carbonic anhydrase II and factor VII, genes with structural or control loci assigned to chromosome 8,¹⁸ were not reduced, but the deletion observed in our patients probably involved a number of other genes, resulting in dysmorphology and the neurologic findings.

The pattern of inheritance in this family is unusual in that two siblings were affected whereas the parents and a third sibling were chromosomally normal. Cytogenetic analysis on a fourth sibling has not yet been performed, but the child has a normal physical exam and hemoglobin values. Studies of blood groups and HLA antigens in this family were consistent with the presumed paternity. Although other possible mechanisms may explain our observations, the most likely explanation is that one parent is mosaic for this abnormality.

It is likely that congenital spherocytic anemias are a heterogeneous group of disorders but, other than a deficiency of α and β spectrin described in a small number of patients,¹⁹

Fig 3. Sodium dodecyl sulfate 3.5% to 7.5% gradient polyacrylamide gel electrophoresis of RBC ghosts. Gels were stained with Coomassie blue. Shown are the gels of both parents (lanes 1 and 2), affected patients C.H. and B.H. (lanes 3 and 4), and a normal control (lane 5). There were no major differences in membrane protein composition between the affected children, parents, and control.

the results of SDS-PAGE of RBC ghosts derived from peripheral blood of HS patients, as in our two cases, show no qualitative abnormalities.²⁰ Functional studies have detected abnormalities of spectrin-band 4.1 binding²¹ and cytoskeletal structure²² in small groups of patients.

Hemizyosity for a gene on 8p might alter the quantity or function of a membrane protein in a manner not detectable by the semiquantitative gel systems used in this study. For example, an enzymatic deficiency resulting in a failure to modify appropriately a structural protein after translation could affect that protein's binding capacity. Additional studies will be needed to delineate the defect, but these findings

may narrow the chromosomal region in which to search for a gene responsible for spherocytosis; the availability of a cell line* should help in these investigations.

ACKNOWLEDGMENT

We would like to thank Drs Louis Miceli and Edward Klimek for referring the patient and Dr Ted Steck for helpful discussions. Barbara Jones provided technical assistance, and the carbonic anhydrase studies were performed by Dr Richard Tashian.

*A lymphoblastoid cell line from patient B.H. has been placed with the NIGMS Human Genetic Cell Repository, Camden, NJ.

Selective Expression of *fos* Proto-oncogene in Human Acute Myelomonocytic and Monocytic Leukemias: A Molecular Marker of Terminal Differentiation

By F. Mavilio, U. Testa, N.M. Sposi, M. Petrini, E. Pelosi, C. Bordignon, S. Amadori, F. Mandelli, and C. Peschle

Expression of human *fos* proto-oncogene (*c-fos*) was analyzed in primary cells from 50 untreated acute lymphocytic (ALL) and myeloblastic (AML) leukemias. *c-fos* RNA, analyzed by blot hybridization, was detected virtually only in myelomonocytic (M4) and monocytic (M5) AML. Both M4 and M5 samples show a strong positive correlation between the amount of *c-fos* transcripts and the percentage of leukemic cells expressing surface antigens specific

for mature monocytes and macrophages. Normal mature monocytes exhibit a detectable level of *c-fos* RNA, which is virtually unaltered on activation to macrophage differentiation, but is always below that observed in M4 through M5 monocyticlike cells. These data provide evidence that *c-fos* expression is linked to terminal monocyte and macrophage differentiation in normal and leukemic hemopoiesis.

© 1987 by Grune & Stratton, Inc.

THE HUMAN *fos* proto-oncogene (*c-fos*) (ie, the cellular homologue of the transforming gene (*v-fos*) of Finkel-Biskis-Jenkins (FBJ) murine osteosarcoma virus¹ is localized on chromosome 14² and codes for a 380 amino acid nuclear protein of yet unknown function.³ In quiescent human and mouse fibroblasts, transient activation of *c-fos* transcription is detected as soon as 15 minutes after the growth stimulus,⁴⁻⁶ thus implying a role for *c-fos* in cell cycle control. On the other hand, expression of *c-fos* is clearly linked to cell differentiation. Thus, it is enhanced in murine hemopoietic cells or leukemic lines induced by colony-stimulating factors,⁷ as well as in human promyelocytic or monoblastic lines induced by phorbol esters.⁸⁻¹⁰ Furthermore, transfection of cloned mouse *c-fos* into F9 teratocarcinoma cells causes expression of both *fos* mRNA and protein, which is correlated to cell differentiation.^{11,12} Finally, abundant accumulation of *c-fos* transcripts and protein has been observed in late gestation extraembryonic tissues of both murine and human origin.¹³⁻¹⁵

We studied *c-fos* expression in primary cells from 50 untreated human lymphocytic (ALL) and myeloblastic (AML) acute leukemias, accurately classified on the basis of both cell morphology and expression of surface antigen markers. We found significant expression of *c-fos* only in myelomonocytic (M4) and monocytic (M5) AML, with a strong positive correlation between the amount of transcripts and the percentage of leukemia cells expressing surface antigens specific for mature monocytes and macrophages. Expression of *c-fos* was detected even in normal peripheral

blood monocytes, although at a level approximately threefold lower than in leukemic cells.

METHODS

Patients and cells. We selected 50 hematology-oncology patients with acute leukemia of either myelogenous or lymphocytic type. Differential diagnosis of ALL in pre-B, B or T type and of AML in M1 through M5 type was carried out by both morphological evaluation of bone marrow smears according to French-American-British (FAB) criteria¹⁶ and analysis of surface antigen pattern of leukemic cells. All patients were advised of all procedures and attendant risks, and gave informed consent.

Leukemic cells were obtained immediately after diagnosis and before initiation of therapy from peripheral blood or bone marrow aspirates, and enriched up to 90% by centrifugation on Ficoll-Hypaque cushions. Binding of monoclonal antibodies (OKT3, T4, T6, T8, T9, T10, T11, M5, B1, and BA-2 from Ortho Diagnostics, Raritan, NJ; MO2 from Coulter Immunology, Hialeah, FL; Tec-HLA-DR, MG1, and M1 from Tecnogenetics, Turin, Italy; Leu-1 and Leu-2 from Becton Dickinson, Mountain View, CA; R-10, which specifically recognizes human glycoprotein A, generously sent by Dr P.A. Edwards; AN-51 which recognizes human platelet glycoprotein I, kindly provided by Dr A.J. McMichael) was determined by indirect immunofluorescence. Leukemic cells (2×10^6), isolated by centrifugation on a Ficoll-Hypaque cushion, were washed three times in Hank's saline solution and incubated for 60 minutes at 4 °C with 200 μ L of an appropriated dilution in Hank's saline solution containing 1 mg/mL of bovine serum albumin (BSA) of the monoclonal antibody. The cells, washed at 4 °C in Hank's saline solution, were then incubated (60 minutes at 4 °C) with fluorescein isothiocyanate (FITC)-labeled F(ab') fragments of immunoadsorbent-purified sheep antibodies against mouse IgGs. After three additional washes, the cells were mounted on slides in 50% glycerol in phosphate-buffered saline (PBS). The proportion of fluorescent cells was scored in incident light on a Leitz standard universal fluorescent microscope, equipped with a set of filters for narrow-band fluorescence.

Mature resting monocytes were obtained from peripheral blood buffy coat of healthy donors by enrichment on a Ficoll-Hypaque cushion and subsequent purification (>90%) by either centrifugation on a Percoll density gradient¹⁷ or standard adherence on tissue culture flasks.

RNA analysis. Total cellular RNA was extracted from 10^8 cells by the guanidine thiocyanate technique,¹⁸ dotted in 8.0 to 0.5 μ g aliquots onto nitrocellulose paper (BA-85, Schleicher & Schull, Keene, NH), and hybridized¹⁹ to 10^7 cpm of the 1.1-kilobase (kb) *Pst*I/*Pst*I fragment containing most of *v-fos*²⁰, labeled by nick-translation up to a specific activity of 4 to 9×10^8 dpm/ μ g. Stringency of washing (50 mmol/L of NaCl, 5 mmol/L of Na-citrate at 65 °C) was accurately tested on appropriate negative

controls to avoid nonspecific binding or cross-hybridization of the viral probe. Hybridization to a chicken β -actin probe²¹ was carried out to allow normalization of RNA levels. Poly-A⁺ RNAs were obtained by one passage on oligo-dT cellulose columns, run in 5- μ g aliquots on 1% agarose-formaldehyde gels,²² transferred onto nitrocellulose paper by capillary blot, and hybridized as described for dot blots.

DNA analysis. High mol wt DNA was extracted from 10^8 cells, digested with restriction endonucleases, run on 1% agarose gels, transferred onto nitrocellulose paper, and hybridized to 2×10^7 cpm of radiolabeled probe as described.²³

RESULTS

We analyzed a sample of 20 ALL (8 T ALL, 1 B cell precursor, 8 pre-B, and 3 B ALL) and 30 AML (3 M1, 6 M2, 5 M3, 8 M4 and 8 M5 AML). The expression of *c-fos* in purified leukemic cells was quantitatively evaluated by filter hybridization of total RNA to a *fos*-specific probe (Fig 1). *c-fos* transcripts were barely detectable or undetectable in all leukemic samples, with the exception of myelomonocytic (M4) and monocytic (M5) AML cells, which showed variable levels of *fos* RNA (Fig 1). Analysis of poly-A⁺ RNA by Northern blot (Fig 2) indicates that *c-fos* is transcribed into a predominant 2.3-kb mRNA band and a minor 3.6-kb RNA species, probably a precursor. A faint band of 1.9 kb is also detectable, which apparently corresponds to *fos*-related sequences (*r-fos*), transcribed together with *c-fos* after platelet-derived growth factor (PDGF) stimulation of cultured fibroblasts.²⁴ *c-fos* is thus specifically expressed in M4 and M5 AML, both characterized by presence of a variable proportion of neoplastic cells, more or less differentiated along the monocytic-macrophagic pathway. In none of these cases did we observe amplification of the *fos* gene, as evaluated by Southern blot hybridization of genomic DNA (results not shown).

We further investigated whether in M4 and M5 AML samples expression of *c-fos* was related to the number of monocyticlike cells and/or their stage of differentiation. The former parameter was evaluated on the basis of morphological and cytochemical features (ie, inhibition of α -naphthyl acetate esterase staining after treatment with sodium fluoride, which is specific for monocytes); these also allowed a more precise classification of the M5 AML in M5A and M5B subtypes according to FAB criteria.^{16,25,26} On the other hand, the stage of differentiation of leukemic cells within the monocytic pathway was evaluated by immunofluorescence studies with a panel of ten monoclonal antibodies. In particular, we used OKM5, MO2, and Tec-M1, which recognize surface antigens selectively expressed on mature monocytes and macrophages,²⁷⁻²⁹ as well as on terminally differentiated leukemic lines induced in vitro by various agents.²⁹ All morphological, cytochemical, and immunologic data are summarized in Table 1.

The levels of *c-fos* RNA, showing a virtually equivalent spread in M4 and M5 AML, were not correlated with the number of monocyticlike cells in each sample, as evaluated by standard cytochemical criteria (Fig 1, Table 1). Conversely, a strong positive correlation was observed between the abundance of *c-fos* transcripts and the number of cells recognized by either OKM5, MO2, or Tec-M1 antibodies, in

Fig 1. Dot blot analysis of the expression of *c-fos* in human myelomonocytic (M4) and monocytic (M5) acute leukemias (AML), as compared with representative cases of myeloblastic (M1 and M2) and promyelocytic (M3) AML. Total RNA was dotted onto nitrocellulose paper and hybridized to a *v-fos* probe (described in the Materials and Methods section). Autoradiograms were scanned by densitometry, and the values obtained are indicated in Table 1 and plotted in Fig 3. Letters a through j identify the following cases in Table 1: a = MA-82; b = AS-3; c = TO-190; d = LE-104; e = CR-144; f = PR-132; g = DSL-113; h = BA-208; i = VA-134; and j = UMC-122.

both M4 and M5 samples (Fig 3). Among M5 AML, *c-fos* transcripts were more abundant in the M5B subtype (Table 1), which is characterized by a more elevated number of cells morphologically resembling mature monocytes, according to the FAB criteria.

We further investigated *c-fos* expression in normal monocytes. *c-fos* transcripts were clearly detected in nonadherent resting monocytes isolated by centrifugation on density gra-

FAB, classification according to the French-American-British criteria.¹⁶ ND, not determined; Neg, negative; NASDA, α naphthyl acetate esterase activity; NASDA-F, NASDA after Na fluoride inhibition.

dient, at a level ~threefold lower than in leukemic cells (as calculated after normalization for the percentage of leukemic cells expressing terminal monocytic markers). On the other hand, monocytes allowed to adhere for 4 hours did not show any detectable variation in *c-fos* expression, as compared with cells before adherence.

We also observed abundant *c-fos* transcription in a single case of M2-AML (Fig 2). These cells were >70% reactive with MO2, even though no other monocytic features could be demonstrated by morphological, cytochemical, and surface antigen criteria.

DISCUSSION

Growing evidence accumulated in the last years suggests a role for "activated" cellular proto-oncogenes (*c-onc*) in establishment, maintenance and progression of neoplastic growth, particularly in the hemolymphopoietic system.³⁰⁻³³ In this regard, abnormal *c-onc* expression, at both quantitative and qualitative levels is significantly associated to different types of human leukemias and lymphomas: however, cause-effect relationship(s) between these abnormalities and oncogenesis of hematopoietic tumors have not been conclusively established so far.³⁴

Previous studies on *c-onc* expression in leukemias have met with various limitations. A crucial aspect is that most observations have been carried out on leukemic lines, which do not often represent faithfully both the genotype and phenotype of the original neoplastic clone(s).³⁵ On the other hand, interpretation of the limited number of studies carried out on primary cells is hampered by both the small number of examined samples and the poor classification of leukemic cells.^{36,37}

We studied the expression of *c-fos* in primary cells from both lymphocytic and myeloblastic acute leukemia patients. Our data indicate that accumulation of *c-fos* transcripts is limited virtually to the myelomonocytic and monocytic sub-

types. The amount of *c-fos* transcripts appears to be strongly correlated with the number of cells expressing surface markers specific for mature monocytes and macrophages, whereas no correlation exists with the number of monocyticlike cells recognized by conventional cytochemical analysis. We interpret these findings to suggest that leukemic cells expressing surface antigens specific for terminal monocytic differentiation selectively accumulate *c-fos* transcripts (ie, the amount of *fos* RNA detected by blot hybridization in the overall sample depends essentially on the relative number of these cells). Therefore, expression of *c-fos* does not generally occur in leukemic cells belonging to the monocytic lineage (eg, monoblasticlike or promonocyticlike elements), but only in the more differentiated ones, as defined by expression of specific surface markers. Accordingly, *c-fos* transcripts in M5 AML are particularly abundant in M5B samples, which are characterized by the presence of a more elevated number of cells resembling mature monocytes at morphological and cytochemical level (Table 1).

Interestingly, a single case of M2-AML abundantly expressed *c-fos* RNA. These cells were strongly positive to one of the monocyte-specific antibodies (ie, MO-2), even though no other monocytic feature could be demonstrated by morphological, cytochemical or surface antigen criteria. This confirms that *c-fos* expression is linked to the genetic program of terminal monocyte differentiation: occasionally, this program may be partially expressed by leukemic cells otherwise differentiated into a nonmonocytic pathway, as a typical example of lineage infidelity.³⁸

Our results also reflect on previous studies on HL-60 (promyelocytic) and U937 (monoblastic) human leukemic lines, which indicated that addition of 12-*O*-tetradecanoylphorbol-13-acetate (TPA) triggers early *c-fos* transcription and differentiation to adherent macrophages.^{9,10} Interpretation of these studies is rendered uncertain by observations reporting that TPA (as well as other activators of protein kinase C) also induces *c-fos* transcription in various hemo-

Fig 3. Correlation between expression of *c-fos* (percentage of maximum) and reactivity to monoclonal antibodies OKM5, MO2, and Tec-M1 (percentage of positive cells) in M4 (solid circles) and M5 (open circles) AML cases. The amount of *c-fos* transcript was evaluated by dot blot analysis at total RNA (Fig 1). Reactivity to monoclonal antibodies was assessed by indirect immunofluorescence (described in Materials and Methods Section).

poietic-nonmonocytic or nonhemopoietic lines.^{39,40} Our results strengthen the conclusion that the enhanced *c-fos* transcription in TPA-treated HL-60 and U937 lines may be linked, at least in part, to the induction of terminal monocytic and macrophage differentiation.

A key aspect emerging from our observations is that *c-fos* transcripts are accumulated in normal peripheral blood monocytic cells. We show that the accumulation of *c-fos* transcripts is physiologically linked to terminal differentiation of normal monocytes and is further maintained when they mature to macrophages. Leukemic monocytic cells accumulate *c-fos* transcripts at a level more elevated than that observed in their normal counterparts, however (Fig 2). This discrepancy may hardly be attributed to the more elevated cycling activity of leukemic v normal cells, since M4 through M5 AML elements are mostly blocked in the G0

through G1 through phase of cell cycle.⁴¹⁻⁴³ Indeed, expression of *c-myc*, generally correlated to proliferative activity, is barely detectable in M4 through M5 cells, whereas it is clearly demonstrable in other AML subtypes (M1, M2, M3) showing more intensive proliferation (results not shown here).

In conclusion, our studies provide evidence that *c-fos* transcripts are selectively accumulated in leukemic cells characterized by expression of antigen markers specific for normal mature monocytes and macrophages. In this respect, *c-fos* expression in M4 through M5 AML cells mimics that observed in their normal hemopoietic counterparts, but at a more elevated level. Therefore, expression of *c-fos* may be considered a molecular marker of monocytic differentiation in leukemic cells, possibly of diagnostic significance. Further studies are necessary to assess whether the apparently enhanced expression of *fos* gene in M4 through M5 cells plays a significant role in the leukemogenic process.

Canine Pluripotent Hematopoietic Stem Cells and CFU-GM Express Ia-like Antigens as Recognized by Two Different Class II-Specific Monoclonal Antibodies

By Friedrich Schuening, Rainer Storb, Sondra Goehle, Joey Meyer,
Theodore Graham, H. Joachim Deeg, and John Pesando

A previous study showed failure of autologous engraftment in lethally irradiated dogs when marrow was treated before infusion with anti-class II antibody 7.2 and complement. The current study extended this observation to a second monoclonal antibody (HB10a) that identifies a different determinant on Ia-like molecules. These results suggest the presence of Ia-like antigens on pluripotent hematopoietic stem cells or on "accessory cells" needed for sustained engraftment to occur. To distinguish between these two possibilities, stem cell-depleted Ia-positive peripheral blood leukocytes obtained by discontinuous albumin density gradient were added as probable source of accessory cells to the marrow inoculum that was depleted of Ia-positive cells by treatment with antibody 7.2 and complement. Eight of ten dogs failed to show engraftment, providing further support for the hypothesis that

pluripotent stem cells and not accessory cells were affected by cytolytic treatment. To provide direct evidence for the presence of Ia-like antigens on canine pluripotent hematopoietic stem cells, autologous transplants were performed using 0.7 to 13×10^6 Ia (7.2)-positive marrow cells per kg obtained with the help of fluorescence-activated cell sorter. Of three evaluable dogs, two showed sustained and complete engraftment, indicating that Ia-like antigens, as recognized by anti-class II antibody 7.2, are expressed at least on part of canine pluripotent hematopoietic stem cells. Concurrent in vitro studies revealed that canine CFU-GM also express Ia-like antigens as recognized by the class II-specific monoclonal antibodies 7.2 and HB10a.

© 1987 by Grune & Stratton, Inc.

THE DLA-D region in dogs is thought to be analogous to the I region of the murine major histocompatibility complex and to the HLA-D region in man. In both mouse and man, these regions code for polymorphic bimolecular glycoprotein complexes with molecular weight of approximately 29,000 and 34,000 dalton.¹ There is evidence for the expression of Ia-like antigens in the dog consisting of bimolecular glycoprotein complexes similar to those described in man and mouse.² Ia-like antigens play a crucial role in mediating the cell interactions required in the generation of the immune response.³ Murine and human Ia-like antigens are expressed on B cells, monocytes, and activated T cells. The distribution of Ia-like antigens in dogs appears to differ from that reported for mouse and man in that they are expressed not only on B lymphocytes, monocytes, and activated T cells, but also on most unstimulated T cells.¹

Expression of Ia-like antigens has been demonstrated on human committed hematopoietic precursor cells BFU-E and CFU-GM.^{9,10,25} Controversial results have been published concerning the expression of Ia-like antigens on human

CFU-E.^{8,10,16,21,23-25,27} For lack of an assay for human pluripotent hematopoietic stem cells, it is not presently possible to determine whether Ia-like antigens are expressed on stem cells required for engraftment. Using an in vitro assay for multipotential precursor cells (CFU-GEMM) that represent primitive precursors of multiple lines of hematopoietic differentiation, several groups of investigators have shown that Ia-like antigens are expressed on these very immature hematopoietic precursor cells.^{8,11,17,25} Controversial results have been published concerning the expression of Ia-like antigens on those immature precursor cells responsible for generation of committed progenitor cells in liquid long-term hematopoietic cell cultures.^{18,53-55} Three genetic loci coding for distinct Ia-like molecules have been identified in man, DR, DP, and DQ locus. While HLA-DR and DP antigens have been detected on human CFU-GM, BFU-E, CFU-meg, CFU-GEMM, and, by some investigators, HLA-DR antigens on progenitor cells in long-term cultures, HLA-DQ antigens appear not to be expressed on these hematopoietic progenitor cells.^{8,16,55-58}

The function of Ia-like antigens on hematopoietic precursor cells is unknown, although there is evidence that they may be involved in mediating suppression and/or stimulation of these cells.^{20,24,28} Our previous studies have suggested but not unequivocally demonstrated the presence of Ia-like antigens on canine pluripotent hematopoietic stem cells, as demonstrated by failure of autologous engraftment in lethally irradiated dogs when marrow was treated before infusion with monoclonal anti-class II antibody 7.2 and rabbit complement.²⁹ This result could be due either to the presence of Ia-like antigens on pluripotent hematopoietic stem cells or on accessory cells required for sustained stem cell engraftment to occur.

The present study was aimed at distinguishing between these two possibilities by using "addback" of Ia-positive stem cell-depleted peripheral blood leukocytes to Ia-negative marrow cells and by carrying out grafts with positively selected Ia-positive marrow cells. We also extended our

initial observation by using a different monoclonal antibody, HB10a, directed against a second epitope on Ia-like antigens. Finally, we studied the expression of Ia-like antigens on committed hematopoietic precursor cells giving rise to CFU-GM.

MATERIALS AND METHODS

Dogs. Beagles, hounds, and mongrels raised at the Fred Hutchinson Cancer Research Center or purchased from commercial kennels were dewormed, vaccinated against distemper, leptospirosis, hepatitis, and parvovirus, and observed for disease for at least 2 months. The dogs weighed 7.5 to 14.3 (median 10.0) kg and were 7 to 17 (median 10.3) months old at the time of transplantation. Research was conducted according to the principles enunciated in the "Guide for Laboratory Animal Facilities and Care" prepared by the National Academy of Sciences—National Research Council.

Monoclonal antibodies (MAbs). MAb 9.6 (IgG2b)³⁰ and MAb 7.2 (IgG2b)³¹ were kindly provided by Dr Paul Martin of this institution. MAb 9.6 does not cross react with canine cells¹ and was used as the negative control antibody in immunofluorescence studies. MAb 7.2 reacts with HLA-DR antigens and cross reacts with Ia-like antigens on canine cells (Fig 1).⁵² MAb HB10a (IgG2a),³² provided by Dr Edward Clark (University of Washington, Seattle), recognizes HLA-DR and -DP antigens⁵³ and cross reacts with canine Ia-like antigens (Fig 1).

Identification of canine Ia-like antigens. Canine peripheral blood mononuclear cells were isolated by Ficoll-Hypaque (Pharmacia, Piscataway, NJ) density gradient centrifugation. Cells were then cultured in Waymouth's medium supplemented with Concanavalin A (20 µg/mL) and 10% canine serum for 48 hours in a humidified 7% CO₂ atmosphere. Washed cells had a viability of greater than 90% and were suspended in phosphate-buffered saline (PBS) at 30 × 10⁶ cells/mL. Cells were surface labeled with ¹²⁵I (1 mCi per 30 × 10⁶ cells) using the lactoperoxidase method as described previously.⁵² Labeled cells were washed in PBS supplemented with 5 mmol/L KI and lysed with Tris-HCl buffered Triton X-100. Nuclei were pelleted by centrifugation and the lysate applied to a Sephadex G-25 column to isolate labeled proteins. Lysates were precleared by incubation with Protein A-Sepharose followed by centrifugation. Immune precipitation was performed by incubating lysate obtained from approximately 1 × 10⁶ cells with additional Protein A-Sepharose that had been incubated overnight with the appropriate mAb. Radiolabeled samples were eluted from washed pellets by heating for three minutes at 95 °C in reducing sample buffer. Antigens were resolved by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) using a 10% to 15% gradient slab gel and visualized by autoradiography.

Total body irradiation, marrow infusion, and postgrafting care. Bone marrow was harvested from anesthetized dogs as previously described³³ and treated as described below. After marrow aspiration, dogs were given 9.2 Gy of total body irradiation at 7 cGy/min from two opposing ⁶⁰Co sources.³⁴ In vitro treated bone marrow was infused within 2 to 14 hours of irradiation. Postgrafting parenteral fluids, electrolytes, platelet transfusions, and antibiotics were administered as indicated.³³ All blood products used for transfusions were irradiated in vitro (15 Gy) to inactivate pluripotent stem cells and immunologically competent cells. Hematocrit, leukocyte, platelet, and differential counts were obtained daily after transplantation. Autopsies with histological examinations were performed on all dogs that died.

Cytolytic treatment of bone marrow. Ia-positive bone marrow cells were eliminated by treating the marrow with mAb and complement (C') as follows:

Bone marrow was diluted 1:3 with Waymouth's medium and

Fig 1. Identification of iodinated Ia-like antigens on canine mononuclear cells by immune precipitation and SDS-PAGE. Characteristic heterodimeric antigens were identified by the HLA class II-specific mAbs used in these experiments. The following mAbs were assayed: A, J-5 (anti-CALLA); B, ISCR3; C, 7.2; D, 9-49; and E, HB10a. Molecular weight standards consist of ¹⁴C-labeled ovalbumin (43 kd) and carbonic anhydrase (30 kd) purchased from New England Nuclear.

separated by density gradient centrifugation over Ficoll-Hypaque (density 1.077) at 1,000 g for 30 minutes. Cells at the interface were washed three times, resuspended to 1 × 10⁶ cells/mL in Waymouth's medium, and incubated with Protein A-Sepharose-purified mAb 7.2 or HB10a (1 mg/10⁹ cells) at room temperature for 60 minutes. The cells were then pelleted and the supernatant was stored at -20 °C for later testing for residual antibody activity (see below). After three further washes, the cells were incubated with undiluted rabbit C' of prescreened batches (absorbed for DR typing, Pelfreeze, Rogers, AR; 1 × 10⁹ cells/50 mL) at room temperature for 60 minutes. The cells were then washed three times and the incubation with C' was repeated. After three washes, the cell pellet was resuspended to 30 mL and infused into the irradiated dog.

Two dogs received marrow cells obtained by density-gradient centrifugation over Ficoll-Hypaque treated twice with C' only as described above but without prior incubation with mAb.

Immunofluorescence studies. In order to determine the efficiency of the cytolytic treatment, bone marrow cells were examined for Ia+ cells before and after incubation with mAb and C' using indirect immunofluorescence and flow microfluorometry. The staining procedure has been described.¹ Briefly, samples of marrow were incubated with mAbs 9.6, 7.2, or HB10a at saturation for 30 minutes at 4 °C. The cells were then washed and incubated with a 1:20 dilution of fluorescein isothiocyanate-conjugated F(ab')₂ fragments of goat antimouse IgG (Tago, Burlingame, Calif). After further washing, cells were analyzed with a fluorescence-activated cell sorter FACS 440 (Becton Dickinson FACS Systems, Sunnyvale, Calif). Positively labeled cells were defined as having fluorescence greater than background fluorescence using mAb 9.6.

Cell sorting. To investigate the characteristics of Ia-positive marrow cells, we collected those cells using a FACS 440 cell sorter. Bone marrow cells obtained by density gradient centrifugation over Ficoll-Hypaque were stained with mAb 9.6, 7.2, or HB10a and fluorescein isothiocyanate-conjugated F(ab')₂ fragments of goat antimouse IgG as described above. Cells were then suspended in Waymouth's medium at a concentration of 5 × 10⁶ cells/mL and sorted into labeled and unlabeled populations on the FACS 440 at a flow rate of 3,000 cells/sec. Fluorescence intensity of the positively sorted cells was greater than that of 99% of cells stained with irrelevant control mAb 9.6. One dog (C108) receiving 7.2 positive autologous marrow cells could not be evaluated because it died in the first week after marrow transplantation from intercurrent infection.

Cell separation by discontinuous albumin density gradient centrifugation. We used a discontinuous albumin density gradient to

deplete or enrich for hematopoietic precursor cells. Peripheral blood lymphocytes and bone marrow cells were separated by density gradient centrifugation over Ficoll-Hypaque. Interface cells were treated with hemolytic buffer (0.155 mol/L ammonium chloride) and separated by a discontinuous albumin density gradient as described by Dicke.³⁵ The stock solution of bovine serum albumin (BSA; 35%) was made using Sigma Fraction V Powder (Sigma Chemical Co., St Louis, Mo). Eighteen mL of a 27% (w/v) BSA solution in Tris buffer were placed in a glass tube (17 × 2 cm) and followed sequentially by 3.75 mL aliquots of solutions containing 25%, 23%, 21%, and 19% BSA. The cell suspension was layered in 9 mL of 17% BSA on top of the gradient. Total cell load per gradient was 0.1 to 1.3 × 10⁹. The osmolality of the Tris buffer and the albumin stock solution was 350 mosmol. The gradient was then centrifuged at 1,000 g for 30 minutes at 10 °C.

CFU-E assay. CFU-E assays were carried out as described.³⁶⁻³⁸ Briefly, bone marrow cells were cultured at a concentration of 2 × 10⁴ cells/0.1 mL plasma clot together with PBL at a concentration of 2 × 10⁴ cells/clot. Cells were incubated for 72 hours in the presence of 1.0 U of erythropoietin (Step III, sheep plasma, Connaught Lab, Willowdale, Canada) per 1 mL of culture medium. Clots were harvested, fixed on glass slides, and stained with benzidine. Aggregates of eight or more hemoglobinized cells were counted as erythroid colonies.

CFU-GM. CFU-GM were carried out as described.³⁹ 0.075 × 10⁶ mononuclear bone marrow cells separated over Ficoll-Hypaque gradient have been cultured per plate for ten days at 37 °C in a humidified 10% CO₂ incubator in 35 mm plastic Petri dishes containing 2 mL of agar medium. The agar medium consisted of an equal volume mixture of 0.6% (w/v) Bacto-agar (Difco, Detroit, Mich) and double-strength Dulbecco's Modified Eagle's Medium (GIBCO, Grand Island, NY) containing 40% (v/v) heat-inactivated human AB plasma. PHA-stimulated lymphocyte-conditioned medium was added to the Petri dishes (0.1 mL/plate) prior to the agar-medium mixture containing the bone marrow cells.

RESULTS

Autologous transplants with marrow treated by mAb 7.2 and C' and added stem cell-depleted Ia-positive peripheral blood leukocytes. We first showed that treatment of marrow with C' alone does not interfere with engraftment (Table 1, dogs C46 and C142). Then, in confirmation of results by others, we determined that peripheral blood leukocytes from fraction 5 of albumin density gradient were depleted of hematopoietic stem cells insofar as they failed to achieve hematopoietic reconstitution after lethal irradiation (Table 1, dog C86). By further characterizing peripheral leukocytes in fraction 5 using differential counts and flow microfluorometry, we showed that 63 ± 11% of the cells are lymphocytes, 4 ± 2% monocytes, 34 ± 11% polymorphonuclear granulocytes, and that 72 ± 18% of the cells reacted with anti-class II mAb 7.2, 78 ± 15% with anti-class II mAb HB10a, and 66 ± 11% with anti-Thy1 mAb F3-20-7 (data represent mean value ± 1 SD of three independent experiments).

Next, 10 dogs received marrow cells treated in vitro with mAb 7.2 and C' before infusion. The number of mononuclear marrow cells infused after in vitro treatment ranged from 0.2 to 2.4 × 10⁸/kg (Table 1). In addition, eight of the 10 dogs received between 0.04 to 0.9 × 10⁸/kg of Ia-positive peripheral blood leukocytes from fraction 5 of albumin density gradient. To increase the number of stem cell-depleted Ia-positive peripheral blood leukocytes, two of the 10 dogs received cells from albumin density gradient fractions 4 and 5 (Table 1, dogs C122 and C115).

In two of the 10 dogs, marrow incubation with mAb 7.2 and C' was carried out at 5 °C (dogs C106 and C107). This

resulted in incomplete killing of Ia-positive marrow cells as documented by the finding of 7.2 and HB10a-positive cells subsequent to marrow incubation (Table 1). Both dogs showed sustained and complete hematopoietic engraftment. In the remaining eight dogs, marrow was treated at room temperature, which resulted in complete elimination of Ia-positive cells as detected by mAb 7.2 and HB10a in 5 dogs and only 1% to 2% residual Ia-positive cells in 3 dogs as detected by mAb 7.2. These eight dogs failed to show sustained hematopoietic engraftment despite the addition of Ia-positive peripheral blood mononuclear cells. Supernatants from marrow treated with mAb 7.2 and C' were tested for residual antibody by incubating 1×10^6 normal canine peripheral blood mononuclear cells with 100 μ L of the supernatants and then fluorescein isothiocyanate-conjugated F(ab')₂ fragments of goat antimouse IgG. All supernatants reacted with the target cells, confirming that conditions of antibody excess were met.

Autologous transplants with Ia (7.2)-positive marrow cells obtained by fluorescence-activated cell sorting. Additional studies were designed to provide direct evidence for the presence of Ia-like antigens on canine pluripotent stem cells. Marrow cells were separated by Ficoll-Hypaque gradient and then split into fractions using the discontinuous albumin density gradient. A marked enrichment of committed hematopoietic precursor cells, CFU-GM and CFU-E, was seen in

fraction 3 of the gradient (Table 2). Autologous transplants of cells from fraction 3 resulted in prompt, sustained, and complete hematopoietic engraftment (Table 3, dogs C116 and C141). To exclude the possibility, that coating of marrow cells with mAb 7.2 interferes with engraftment, we performed autologous transplants using marrow cells incubated with mAb 7.2 in the absence of C'. Both dogs so treated showed sustained engraftment (Table 3, dogs C124 and C117).

Marrow cells obtained in fraction 3 of the albumin density gradient were then stained at saturation with antibody 7.2 and fluorescein isothiocyanate-conjugated F(ab')₂ fragments of goat antimouse IgG. 7.2-positive cells were selected on the fluorescence-activated cell sorter and infused into lethally irradiated autologous recipient. FACS analysis after cell sort demonstrated that 99% of the positively sorted cells had fluorescence intensity greater than that of cells stained with irrelevant control mAb 9.6. Transplantation results are shown in Table 3, group 3. Dog C134 received 0.007×10^8 cells/kg body weight. This dog showed a rise in white blood cell count on day 9 after marrow transplant, with 60% of the cells being granulocytes. The dog died on day 11 after marrow transplant due to septicemia. Marrow histology at autopsy showed 2% of normal cellularity identifying myeloid as well as erythroid precursor cells. In order to increase the number of 7.2-positive marrow cells transplanted into the dogs, we increased the duration of the cell sort and used two cell sorters simultaneously. As a result dogs C228 and C281 received 0.03 and 0.13×10^8 marrow cells/kg body weight, respectively. Both dogs showed sustained hematopoietic engraftment and are now surviving longer than 210 days after marrow transplant with complete recovery of marrow function. Speed of neutrophil and platelet recovery was prolonged compared to control dogs and varied depending on number of marrow cells transplanted. Dog C228 receiving 0.03×10^8 marrow cells/kg body weight had granulocyte counts above 1,000 granulocytes/ μ L on day 26, compared to a median of 12 days (range 8 to 14 days) in controls.⁵¹ Platelet counts were above 20,000 platelets per μ L on day 52 (median in control dogs day 15, range 11 to 23 days). Dog C281 receiving 0.13×10^8 marrow cells/kg body weight had

>1000 granulocytes/ μ L already on day 16 and >20,000 platelets/ μ L on day 38.

Autologous transplants with bone marrow treated in vitro with mAb HB10a and C'. In an attempt to extend our previous results obtained with mAb 7.2, we performed autologous transplants using marrow treated with a different anti-class II mAb, HB10a, and C'. Both mAbs identify characteristic heterodimeric complexes by immune precipitation on iodinated Ia-positive canine cells (Fig 1). MAb HB10a identifies both HLA-DR and -DP molecules on human cell populations on which mAb 7.2 is HLA-DR specific, indicating that these two mAbs identify different antigenic determinants.⁵² This conclusion is further supported by the observation that these two Ia-specific mAbs differ in their cross reactivity with additional animal species (Ladiges et al, unpublished). It remains to be determined whether or not these two mAbs identify distinct populations of Ia-like molecules in the dog. Four of five dogs failed to show sustained hematopoietic engraftment (Table 4). The fifth dog (C120) had slow recovery of granulocyte and platelet counts after marrow transplantation. Granulocyte counts were above 1,000 granulocytes/uL on day 26, compared to a median of 12 days (range 8 to 14 days) in controls.⁵¹ Platelet counts were above 20,000 platelets/uL on day 42 (median in control dogs, day 15, range 11 to 23 days).

Hematopoietic in vitro studies. Concurrent in vitro studies revealed that treatment of marrow cells with mAb 7.2 and C' as well as with mAb HB10a and C' impaired growth of CFU-GM (Table 5). Expression of Ia-like antigens by CFU-GM was in addition examined by sorting 7.2-positive and -negative marrow cells and plating them in CFU-GM assay. Only 7.2-positive marrow cells showed growth of CFU-GM (Table 5). Similar results were obtained after plating HB10a-positive and -negative marrow cells in CFU-GM (Table 5).

DISCUSSION

We have previously shown that dogs given lethal total body irradiation and an infusion of autologous marrow treated in vitro with anti-class II mAb 7.2 and rabbit C' failed to achieve hematopoietic reconstitution.²⁹ In our present study, we extended these observations with mAb 7.2 to a different anti-class II mAb, HB10a, which recognizes HLA-DR and -DP antigens⁵² and cross reacts with Ia-like antigens on canine cells (Fig 1). These results provide additional

circumstantial evidence favoring the presence of Ia-like antigens on canine pluripotent stem cells.

Another explanation for the failure of engraftment seen with antibody-treated autologous marrow is that Ia-like antigens are not expressed on pluripotent hematopoietic stem cells but rather on "accessory" cells required for stem cells to engraft. We tried to distinguish between these two possibilities by adding stem cell-depleted Ia-positive peripheral blood leukocytes to a marrow inoculum that was depleted of Ia-positive cells, thereby presumably providing accessory cells. As it is possible to achieve complete marrow repopulation after otherwise lethal total body irradiation with peripheral blood cells only, this cell population contains stem cells as well as accessory cells and therefore can be used as a source for accessory cells. However, eight of ten dogs so treated failed to show sustained hematopoietic engraftment. This result provided further support for our hypothesis that Ia-like antigens as detected by anti-class II mAb 7.2 are expressed on canine pluripotent stem cells. The sustained engraftment seen in two of the ten dogs was most likely due to the fact that incubation with antibody and C' was carried out at 5 °C rather than at room temperature, resulting in incomplete elimination of Ia-positive cells from the marrow.

It is possible, of course, that if those dogs receiving Ia-depleted marrow had survived longer, reconstitution of hematopoiesis might have occurred. With existing supportive measures, this possibility cannot presently be investigated. We therefore tried to test the hypothesis of expression of Ia-like antigens on pluripotent canine stem cells directly by carrying out grafts with marrow cells positively selected for Ia-like antigens as detected by anti-class II mAb 7.2 using the fluorescence-activated cell sorter. Of the evaluable three dogs, one had only transient hematopoietic engraftment, most likely due to very low marrow cell numbers infused (7×10^5 /kg). With an increase in the duration of the cell sort, we increased the number of Ia-positive marrow cells transplanted. Two subsequent dogs given 3 and 13×10^6 Ia-positive marrow cells/kg showed sustained and complete hematopoietic engraftment. This result is in keeping with our hypothesis, and provides direct evidence for the expression of Ia-like antigens as detected by anti-class II mAb 7.2 on at least part of pluripotent canine hematopoietic stem cells.

Prendergast et al⁶⁰ recently described complete although slow marrow recovery in a total of 7 out of 10 dogs after lethal TBI and infusion of autologous Ia-depleted marrow using a different anti-class II mAb (WM-2). These results are in contrast to what we have seen using two different

anticlass II mAbs and may either be due to incomplete elimination of Ia-positive marrow cells or to differential expression of Ia-like antigens as recognized by mAbs 7.2, HB10a, and WM-2 on canine pluripotent hematopoietic stem cells. Efficiency of removal of Ia-positive marrow cells was analyzed by fluorescence microscopy counting 200 cells rather than by fluorescence-activated cell sorter counting 4,000 cells. Engraftment was seen only in those dogs receiving a relatively high mean cell dose of $9.4 \times 10^7/\text{kg}$ compared to those dogs that failed engraftment (mean cell dose $3.5 \times 10^7/\text{kg}$), suggesting that the first group might have received a sufficient number of remaining Ia-positive marrow cells to allow marrow recovery. Unfortunately the authors did not provide data of transplants performed with marrow cells positively selected for Ia-like antigens as detected by mAb WM-2.

Detection of Ia-like antigens on most of human committed hematopoietic precursor cells,^{4-9,12-14,16,19,20,26,27} and the demonstration of Ia-like antigens on human B lymphocytes and monocytes⁴³⁻⁴⁵ as well as on human lymphocytic and myelocytic leukemia cells,^{26,45} have prompted the suggestion that human pluripotent hematopoietic stem cells also express Ia-like antigens. For lack of an assay for human pluripotent hematopoietic stem cells, it is not presently possible to prove this hypothesis directly. An in vitro assay for multipotential progenitor cells (CFU-GEMM, colony-forming units: granulocyte, erythroid, monocyte, megakaryocyte) has been developed.⁴⁶ These human multipotential progenitors may be closely related to murine CFU-S in that they represent primitive precursors of multiple lines of hematopoietic differentiation. Several groups of investigators have shown that Ia-like antigens are expressed on these very immature hematopoietic precursor cells.^{8,11,17,25} Controversial results have been published concerning the expression of Ia-like antigens on those immature precursor cells responsible for proliferation of committed progenitor cells in liquid long-term hematopoietic cell cultures. Moore et al¹⁸ could not identify Ia-like antigens on those progenitor cells in long-term cultures. However, Andrews et al⁵³ found inhibition of hematopoietic precursor cells in a similar long-term culture system after treatment with anti-HLA-DR antibody and C'. Keating et al⁵⁴ could not detect Ia-like antigens on precursor cells responsible for the proliferation of CFU-GM in a different

(one stage) long-term culture system. In all these studies, only depletion techniques were used to identify Ia-like antigens on precursor cells, giving rise to long-term culture systems. Recently, Falkenburg et al⁵⁵ showed the expression of HLA-DR determinants on precursor cells responsible for sustained proliferation of CFU-GEMM, BFU-E, and CFU-GM in liquid long-term cultures, using both fluorescence-activated cell sorting and C'-dependent cytotoxicity assays. Three genetic loci coding for distinct Ia-like molecules have been identified in man, DR, DP, and DQ locus. While HLA-DR and DP antigens have been detected on human CFU-GM, BFU-E, CFU-meg, CFU-GEMM, and, by some investigators, HLA-DR antigens on progenitor cells in long-term cultures, HLA-DQ antigens appeared not to be expressed on these hematopoietic progenitor cells.^{8,16,55-58} However, a recent publication by Sparrow et al describes expression of HLA-DQ antigens on three subpopulations of CFU-GM.⁵⁹

Using the CFU-S assay in mice, Basch et al⁴⁷ have reported that a heteroantiserum against Ia antigens was not reactive with murine CFU-S in cytotoxicity and fluorescence-activated cell sorting studies. They concluded that CFU-S lack Ia antigens. Recent evidence, however, suggests that the situation is more complex. The murine I region is composed of at least five subregions.⁴⁸ Murine Ia antigens encoded by the I-E subregion have amino acid homology with human DR antigens.⁴⁹ Fitch et al⁵⁰ found no effect of monoclonal antibodies against I-A subregion gene products on CFU-S, but potent inhibition of these cells by anti-I-E subregion heteroantibodies and C'. These observations suggest that murine pluripotent hematopoietic stem cells express I-E subregion antigens (equivalent to human HLA-DR) but not I-A subregion antigens (equivalent to human HLA-DQ). Performing autologous marrow transplants in rhesus monkeys, Gerritsen et al²² observed graft failure after incubating the marrow with a combination of anti-RhLA-DR7 antibodies and C', suggesting that the RhLA-DR7 antigen is present on the hematopoietic stem cells of the rhesus monkey. Our previous²⁹ and present results in dogs, showing that Ia-like antigens as detected by anti-class II mAb 7.2 are expressed at least on part of canine pluripotent hematopoietic stem cells, are therefore in agreement with observations reported for human multipotential progenitor cells and for hemato-

poietic stem cells of mice and rhesus monkeys. Most importantly, we showed this to be true not only by methods of negative selection but also by demonstrating complete hematopoietic reconstitution with transplants of cells positively selected for expression of Ia-like antigens as detected by anti-class II mAb 7.2.

Concurrent *in vitro* studies revealed that canine CFU-GM also express Ia-like antigens as recognized by two mAbs (7.2 and HB10a) that identify different determinants on canine Ia-like molecules. We showed this by employing positive and negative selection for the appropriate cells.

Results on canine CFU-GM are in agreement with those reported for man. Both with C'-dependent cytotoxicity assays and fluorescence-activated cell sorting, Ia-like antigens were demonstrated on human CFU-GM using polyclonal and monoclonal antibodies.

Our findings indicate that Ia-like antigens, recognized by anti-class II antibody 7.2, are expressed on most true

pluripotent hematopoietic stem cells in the dog. This seems to be relevant for clinical bone marrow transplantation. Both human and canine lymphoma cells express Ia-like antigens, and transplantation of autologous marrow purged of Ia-positive tumor cells seems an attractive treatment modality. Present results suggest that this may not be safe. At the present time, it is uncertain whether true pluripotent hematopoietic stem cells in man are Ia positive or negative and, if Ia positive, whether they express only HLA-DR but not HLA-DQ, thus allowing selective removal of HLA-DQ-positive neoplastic cells.

ACKNOWLEDGMENT

We wish to thank John Louton, PhD, for expert technical assistance with the cell sorting, Dr Paul Martin for providing monoclonal antibodies 7.2 and 9.6, and Dr Edward Clark for providing antibody HB10a.

Interaction of Ristocetin and Bovine Plasma With Guinea Pig Megakaryocytes: A Means to Enrich Megakaryocytes Based on Membrane Rather Than Physical Characteristics

By Carl W. Jackson, Shirley A. Steward, Nancy K. Hutson, and Richard A. Ashmun

We have investigated whether megakaryocytes can be aggregated by ristocetin and bovine plasma and whether such aggregation can be used as a step in the purification of megakaryocytes from marrow cell suspensions. Guinea pig marrow cell suspensions were first enriched for megakaryocytes by density equilibrium centrifugation in continuous Percoll density gradients. The megakaryocyte-enriched marrow was stirred in a platelet aggregometer to which ristocetin or bovine plasma was added. Megakaryocytes were aggregated by both ristocetin and bovine plasma with the proportion aggregated being related to the concentration of ristocetin or bovine plasma. Maximal aggregation (>90% of megakaryocytes) was achieved with 2.0 mg/mL ristocetin or 5% bovine plasma and required five minutes. All maturation stages of morphologically recognizable megakaryocytes were aggregated. The megakaryocyte aggregates were separated from the marrow suspension by sedimentation at 1 g and the megakaryocytes disaggregated by dilution with media (ristocetin

aggregated) or addition of dextran sulfate (bovine plasma aggregated). Megakaryocyte purity and recovery were higher with bovine plasma than with ristocetin. A mean of 92% of the megakaryocytes in the bovine plasma aggregated cell suspensions were recovered with megakaryocytes constituting an average of 76% of the final cell suspensions. The viability as well as the diameters and DNA content distribution of these megakaryocytes were similar to those of the starting population. We conclude that guinea pig megakaryocytes behave like platelets in that they can be aggregated with ristocetin or bovine plasma and that megakaryocyte aggregation induced by ristocetin or bovine plasma provides a means to enrich these cells based on membrane rather than physical characteristics. This approach yields purified megakaryocyte populations that are representative of those in unfractionated marrow.

© 1987 by Grune & Stratton, Inc.

HIGHLY purified populations of megakaryocytes are required to study many aspects of megakaryocyte differentiation. Most methods of megakaryocyte enrichment employ a sedimentation step in which megakaryocytes are separated from other marrow cells by virtue of their larger size.¹⁻¹¹ Small megakaryocytes that tend to be immature may be selectively lost by such procedures.¹² This problem might be overcome if both large and small megakaryocytes could be specifically aggregated so that all megakaryocytes would sediment together. The observation that bovine von Willebrand factor (vWF)¹³⁻¹⁶ alone and ristocetin¹⁷ in the presence of vWF¹⁸ will aggregate human as well as guinea pig¹⁹ platelets suggested the possibility that megakaryocytes also might be aggregated by these reagents. Platelets so aggregated can be disaggregated if the platelet release reaction is inhibited during aggregation.²⁰ In this study, we have examined whether guinea pig megakaryocytes can be aggregated by bovine plasma and ristocetin and whether such aggregation can be used as a step in the purification of megakaryocytes.

MATERIALS AND METHODS

Young adult male guinea pigs of the Hartley strain were purchased from Hazelton Research Animals (Denver, Pa) or Charles River Breeding Labs (Wilmington, Mass). Ristocetin was purchased from Curtin Matheson Scientific, Inc. (Houston, Tex) and citrated bovine plasma from Hyclone Laboratories (Logan, Utah). Purified bovine von Willebrand factor was a generous gift of Dr E.P. Kirby, Temple University, Philadelphia, Pa. Normal porcine plasma and plasma from a pig with von Willebrand disease were a generous gift of Drs L.A. Solberg and E.J.W. Bowie, Mayo Clinic, Rochester, Minn. Percoll density media was obtained from Pharmacia Fine Chemicals (Piscataway, NJ) and autoclaved before use. Fetal calf serum was obtained from GIBCO (Grand Island, NY).

Collection of marrow and preparation of megakaryocyte-enriched marrow cell suspensions by density fractionation. Guinea pigs were killed by exsanguination under ether or sodium thiamy-

lal anesthesia. Blood was collected from the dorsal aorta into 0.1 mmol/L acid citrate and plasma prepared. Marrow from tibias, femurs, and humeri was flushed with 2.5 mL of CATCH media² containing DNase I³ and suspended by gentle pipetting using Pasteur pipettes siliconized with Prosil 28 (PCR, Inc., Gainesville, Fla). Unless indicated otherwise, later references to CATCH media indicate the above formulation. Cell concentration was determined using a hemacytometer. Initial enrichment of megakaryocytes was achieved by equilibrium density centrifugation in Percoll density gradients based on the studies of Rabellino et al⁵ who found that human megakaryocytes had a lower buoyant density than 90% of the other marrow cells. Stock Percoll density media was made isotonic with 10X Hanks' balanced salt solution (BSS) without Mg⁺⁺ and Ca⁺⁺ and diluted to the desired concentration with CATCH media. A 10 mL continuous linear gradient made of 0% to 36% Percoll density media with a gradient density range of 1.02 to 1.05 g/mL was formed on top of 2 mL of 45% Percoll in a 15 mL plastic centrifuge tube. The continuous gradient was constructed using a linear gradient maker with 5 mL of the above pooled marrow suspension in the low density chamber and 5 mL of 36% Percoll in the high density chamber. A continuous rather than a discontinuous density gradient was used so as to minimize contact of megakaryo-

cytes with each other. The gradient was centrifuged for 20 minutes at 1,000 g at room temperature and the top 10 mL removed including cells in the 36%:45% Percoll interface, diluted 1:1 with CATCH media and the cells pelleted (600 × g). More than 95% of the megakaryocytes were present in this fraction. The supernatant was discarded and the cells resuspended in CATCH media with 12.5 mmol/L Na₂ EDTA¹⁶ to prevent activation (for aggregation studies with bovine plasma) or in CATCH media with various concentrations of fresh, citrated guinea pig plasma plus 5 mmol/L Na₂ EDTA²⁰ and usually 5% fetal calf serum (for ristocetin aggregation).

Aggregation studies with ristocetin and bovine plasma. The megakaryocyte-enriched cell suspension (usually 0.7 mL) was stirred (1,200 rpm) in a platelet aggregometer (Chrono-Log Corp., Havertown, Pa) at 37 °C in a "0.312" diameter siliconized cuvette to which various concentrations of ristocetin or bovine plasma were added. Megakaryocyte aggregation was assessed using phase microscopy by comparing in hemacytometer chambers, the number of single megakaryocytes before and after reaction with ristocetin or bovine plasma.

Enrichment of aggregated megakaryocytes. For enrichment using bovine plasma, megakaryocytes in 700 µL of density-fractionated cell suspension were aggregated with 5% bovine plasma for five minutes. The cuvette was then removed from the aggregometer, placed in a vertical position, and the cells allowed to sediment seven minutes (found to be the optimal time for sedimentation of megakaryocyte aggregates). The supernatant cell suspension was removed and discarded. The sedimented cells were resuspended in 600 µL of CATCH media with 12.5 mmol/L EDTA and 5% bovine plasma and stirred in the aggregometer 30 seconds. The cuvette was removed from the aggregometer and the cell suspension was underlaid with 600 µL of 3% Percoll in CATCH media with 12.5 mmol/L EDTA and 5% bovine plasma. The cells were allowed to sediment seven minutes (found to be the optimal time) after which the supernatant cell suspension was removed. The sedimented cells were resuspended in CATCH media with EDTA and bovine plasma, stirred, underlaid with the 3% Percoll media as above, and allowed to sediment seven minutes. The sedimented cells were resuspended in 5 mL of CATCH media to which 60 µg/mL of dextran sulfate (stock solution = 1 mg/mL in Hanks' BSS without Ca⁺⁺ and Mg⁺⁺) was added. The cell suspension was allowed to stand at least ten minutes. The cells were then concentrated by centrifugation (100 g for five minutes) and resuspended in 0.5 to 1.0 mL of CATCH media for counting, trypan blue exclusion studies, and collection of cells onto slides by cytocentrifugation (Cytospin 2, Shandon Southern Instruments, Inc., Sewickley, Pa). The cytocentrifuge preparations were stained with modified Wright's stain (Hema-Tek stain pak #4481, Miles Scientific, Naperville, Ill) on a Hema-Tek automatic slide stainer, and the percentage of morphologically recognizable megakaryocytes determined to assess megakaryocyte purity.

To compare megakaryocyte enrichment achieved with ristocetin as the aggregating agent to that with bovine plasma, megakaryocytes in CATCH media with 15% guinea pig plasma, 5% fetal calf serum, and 5 mmol/L EDTA were aggregated with 1.75 mg/mL ristocetin for five minutes followed by three differential sedimentations as described above. For the second and third sedimentations, the sedimented cells were resuspended in 600 µL of CATCH media containing 2.0 mg/mL ristocetin, 15% citrated guinea pig plasma, 5% fetal calf serum, and 5 mmol/L Na₂ EDTA. After stirring for 30 seconds, the cells were underlaid with 600 µL of 3% Percoll in CATCH media with the ingredients just described. After the third sedimentation, the megakaryocytes were disaggregated by suspending in 5 mL of CATCH media. The use of 1.75 mg/mL ristocetin during the aggregation step was chosen to give optimal aggregation with minimal plasma protein precipitation. The megakaryocyte

aggregates were better maintained and final megakaryocyte recovery was higher if the ristocetin concentration was slightly higher (2.0 mg/mL) during the second and third sedimentations.

Electron microscopy. Samples were fixed in 2% glutaraldehyde in 0.1 mol/L cacodylate buffer at 4 °C overnight and postfixed with osmium tetroxide for one hour. The samples were dehydrated in ethanol and embedded in resin. Sections were cut and stained 20 minutes in aqueous uranyl acetate, then 20 minutes in Reynolds lead stain.

Measurement of megakaryocyte diameters. For diameter measurements, cells suspended in CATCH media were placed on hemacytometers and visualized by phase-contrast microscopy. Diameters of 75 megakaryocytes in each sample were measured using an eye piece micrometer.

Analysis of DNA content distributions of megakaryocytes by two-color flow cytometry. The DNA content distributions of megakaryocytes in marrow cell suspensions doubly stained with platelet antibody and propidium iodide were analyzed by two-color flow cytometry as previously described.²¹ Briefly, megakaryocytes were specifically labeled with heterologous rabbit antiginea pig platelet antiserum by indirect immunofluorescence using FITC-goat antirabbit IgG/F(ab')₂ (green fluorescence; Tago, Inc., Burlingame, Calif) as the second antibody. One- to two-tenths mL of platelet-depleted guinea pig RBCs were added to the final megakaryocyte suspension after incubation with the platelet antibody to act as a cushion during the washing steps since the purified megakaryocytes were quite fragile. The platelet antiserum was prepared as previously outlined.² After adsorption with guinea pig red cells, the antibody was bound to guinea pig platelets in EDTA, the platelets washed, and the bound antibody eluted with glycine-HCl-saline buffer (pH 2.0) to ensure platelet specificity. The eluted antibody was buffered with phosphate buffer. DNA was stained with propidium iodide (red fluorescence) in hypotonic citrate solution.²² Each stained sample was incubated with RNase (Bovine pancreas, 50 µg/mL, Calbiochem-Behring, San Diego, Calif) for 30 minutes at room temperature prior to flow cytometric analysis to remove RNA-associated propidium iodide staining. The DNA content distribution of megakaryocytes was selectively determined by two-color, green-gated flow cytometric analysis, in which the red and green fluorescence emissions of all cells were analyzed, but only the red fluorescence (DNA content) of cells that specifically bound the platelet antibody was recorded. The green gate for analysis of all samples was selected by examining the green fluorescence distribution of cells with DNA contents ≥8N in unfractionated marrow. The number of cells in each DNA peak was determined by taking the integral from one peak nadir to the next.

RESULTS

Guinea pig megakaryocytes were aggregated by ristocetin and bovine plasma. The aggregates may be several hundred megakaryocytes in size. An example of such a megakaryocyte aggregate is shown in Fig 1. For this preparation, the megakaryocyte-enriched marrow cell fraction suspended in CATCH media was aggregated with 5% bovine plasma.

Characteristics of megakaryocyte aggregation with ristocetin. The dose-response relationship between ristocetin concentration and the degree of megakaryocyte aggregation five minutes after the addition of ristocetin is shown in Fig 2. For this study, the density-fractionated cells were suspended in CATCH medium containing 5% fetal calf serum and 15% guinea pig plasma. Twenty-five percent guinea pig plasma was required to support maximal aggregation with 2.0 mg/mL ristocetin when 5% fetal calf serum was not

Fig 1. Phase-contrast photomicrograph of megakaryocytes aggregated with 5% bovine plasma (40 $\times$ original magnification; 20 $\times$ current magnification).

included. A rather steep dose response was seen with no megakaryocyte aggregation detectable at 0.5 mg/mL ristocetin. About one half of the megakaryocytes were aggregated with 1.0 mg/mL ristocetin. Maximal aggregation (usually >90% of megakaryocytes aggregated) was seen with 2.0 to 2.5 mg/mL ristocetin. Megakaryocyte aggregation was relatively rapid with more than one half of the megakaryocytes aggregated at 30 seconds and about 3/4 aggregated at one minute. Maximal aggregation occurred at five to seven minutes. The ristocetin-induced megakaryocyte aggregates could be disaggregated by diluting out ristocetin.

Characteristics of megakaryocyte aggregation with bovine plasma. The dose-response relationship between bovine plasma concentration and the degree of megakaryocyte aggregation five minutes after addition of bovine plasma is shown in Fig 3. Maximal aggregation was seen with 2.5% to 5.0% bovine plasma. Some aggregation of other marrow cells occurred with 20% bovine plasma. The time course for megakaryocyte aggregation with 5% bovine plasma was similar to that for ristocetin with maximal aggregation occurring within five to seven minutes. The bovine plasma-aggregated megakaryocytes could be disaggregated by the addition of 60 μ g/mL dextran sulfate.

Megakaryocyte aggregation with purified bovine vWF. Maximal aggregation with purified bovine von Willebrand factor occurred at a concentration of 1 μ g/mL (>90% of megakaryocytes aggregated).

Fig 2. Dose-response relationship between ristocetin concentration and percentage of megakaryocytes aggregated (results of two experiments). Each point represents results from aggregation of 700 μ L of cell suspension (containing 15% guinea pig plasma and 5% fetal calf serum) for five minutes. Megakaryocyte concentration was 183,333 and 231,667/mL.

Fig 3. Dose-response relationship between bovine plasma concentration and percentage of megakaryocytes aggregated (results of two experiments). Each point represents results of aggregation of 700 μ L of cell suspension containing 148,889 to 164,444 megakaryocytes/mL for five minutes.

Megakaryocyte aggregation with normal and von Willebrand disease pig plasma. Plasma of a pig with von Willebrand disease lacked specific megakaryocyte-aggregating activity (Fig 4). Plasma of a normal pig showed a megakaryocyte aggregation dose response like that of bovine plasma. At concentrations of $\geq 10\%$, plasmas of both pigs caused aggregation of other marrow cells.

Enrichment of aggregated megakaryocytes. Several procedures were examined for enrichment of the megakaryocyte aggregates including velocity sedimentation in large volume, shallow gradients, filtration through nylon mesh, and differential sedimentation. Of these, a series of differential sedimentations in the aggregation cuvettes have proved most successful. Two sedimentations of the aggregated cells in a 3% Percoll gradient after an initial sedimentation without a Percoll underlay yielded maximal megakaryocyte enrichment and recovery (Table 1). A third sedimentation in the 3% Percoll gradient resulted in lower megakaryocyte recovery without improvement in megakaryocyte purity.

Higher megakaryocyte enrichment was achieved with bovine plasma as the aggregating agent (Table 2). In other experiments in which bovine plasma and ristocetin were not simultaneously compared, aggregation with bovine plasma usually resulted in higher megakaryocyte recovery (data not shown).

Table 3 summarizes megakaryocyte enrichment achieved in seven recent experiments. Megakaryocytes comprised an average of 0.15% of the cells in unfractionated marrow suspensions. The initial density fractionation step resulted in only a 3-fold enrichment because of the relatively low megakaryocyte recovery. After the aggregation and sedimentation steps, megakaryocytes constituted three fourths of the resulting cell suspensions which represents a 165-fold enrichment from the density fractionation step. Megakaryocyte recovery after the aggregation and sedimentation steps averaged 92% of the input number. Viability of megakaryo-

cytes in the final suspension was not significantly different from that in unfractionated marrow.

The appearance of megakaryocytes in a cytocentrifuge preparation made after the complete enrichment procedure is shown in Fig 5. All maturation stages of morphologically recognizable megakaryocytes were represented. The vacuolization observed near the periphery of some megakaryocytes was present before the megakaryocyte aggregation step and

previously has been noted by Levine and Fedorko² after density fractionation and velocity sedimentation and by Berkow et al¹⁰ after counterflow centrifugal elutriation and density fractionation.

Electron microscopic examination of the final megakaryocyte preparations indicated that the plasma and nuclear membranes of most cells were intact; dense granules were evenly distributed in the cytoplasm (Fig 6).

Fig 5. Photomicrograph of a Wright's stained cytocentrifuge preparation of a final megakaryocyte suspension (after density fractionation and the aggregation enrichment procedure; original magnification 250 $\times$; current magnification 112 $\times$).

Next, sizes of the megakaryocytes before and after the aggregation enrichment procedure were compared. Diameters of megakaryocytes in the cell suspension resulting from the density fractionation step were compared to those of megakaryocytes in the final cell suspension (after aggregation, three sedimentations, and disaggregation; Table 4). Both mean diameter and diameter distribution of megakaryocytes in the final preparation were similar to those before aggregation.

Also, we have compared by flow cytometry the DNA content distributions of megakaryocytes enriched by aggregation with bovine plasma to those of megakaryocytes in unfractionated marrow, and after the equilibrium density centrifugation step. It should be pointed out that because we were primarily interested in the DNA distribution of polyploid cells, we chose flow cytometer settings which optimally detected polyploid cells even though this results in some 2N and 4N cells with nonspecific immunoglobulin binding being included as platelet antibody-positive cells. Thus, for the purposes of these analyses, only cells with DNA contents $\geq 8N$ are considered. The ratio of 8N:16N:32N cells after the megakaryocyte enrichment steps was similar to that of unfractionated marrow (Table 5).

Fig 6. Ultrastructure of a relatively mature megakaryocyte after enrichment by density fractionation and the aggregation enrichment procedure (Original magnification 8300 $\times$; current magnification 4980 $\times$).

DISCUSSION

In this study we have asked whether guinea pig megakaryocytes can be aggregated by ristocetin and bovine plasma and if so, can such aggregation be used as a step for megakaryocyte enrichment and purification. Almost all megakaryocytes could be aggregated with ristocetin at a concentration of 2.0 mg/mL in 25% guinea pig plasma or with 5% bovine or porcine plasma. The component in bovine and porcine plasma that induces megakaryocyte aggregation, as with platelet aggregation, appears to be vWF since purified bovine vWF aggregated megakaryocytes while plasma from a pig with von Willebrand disease did not. The aggregated megakaryocytes could be disaggregated by diluting out ristocetin or adding dextran sulfate to bovine plasma-aggregated samples.

Although the mechanism is not well understood, platelet surface glycoprotein Ib seems to be the primary binding site

for von Willebrand factor during ristocetin-induced aggregation.²³⁻²⁷ Bovine vWF also probably reacts with platelet glycoprotein Ib since platelets from patients with Bernard-Soulier syndrome that are deficient in this glycoprotein are not aggregated by this factor.^{28,29} Glycoprotein Ib has been detected on megakaryocytes^{5,30,31} and thus is most likely the site with which ristocetin and bovine plasma interact to produce aggregation of megakaryocytes. It should be pointed out that heparin inhibits platelet aggregation with ristocetin³² and bovine vWF¹⁶ and therefore should not be used as the anticoagulant for marrow collection.

Megakaryocytes enriched using the bovine plasma aggregation step have diameters and DNA content distributions similar to those in unaggregated marrow suspensions. This suggests that megakaryocyte populations produced by this procedure are representative of the original populations. Although we have made no direct comparisons of DNA content distributions of megakaryocyte populations obtained using velocity sedimentation after density fractionation with those enriched by the procedure described here, results of others^{7,12,33} suggest that loss of lower ploidy megakaryocytes can be substantial with the velocity sedimentation step. Taken together, these results suggest that bovine plasma aggregation of megakaryocytes before the sedimentation step allows equal recovery of megakaryocytes of various DNA contents and therefore provides an advantage over velocity sedimentation of single megakaryocytes.

The ability to induce large aggregates of megakaryocytes with ristocetin or bovine plasma also should be useful in electron microscopic studies of these cells since one of the

major obstacles to such studies currently is locating a cell type of such low frequency once the processed marrow specimens are ready for examination.

In situations where megakaryocyte number is reduced to such an extent that megakaryocyte aggregates will not form or are small, the extent of aggregation and size of aggregates might be increased by adding platelets before aggregation so that megakaryocyte-platelet aggregates would be formed. After separation of such aggregates from other cells, the megakaryocytes and platelets could be disaggregated and platelets separated from megakaryocytes if desired.

The ability of ristocetin and bovine vWF to aggregate platelets in plasma is limited to a few species³⁴ possibly because of interference by plasma proteins.^{35,36} Fortunately, platelets of man and guinea pig are readily aggregated by these reagents, but those of other small laboratory animals such as the rat¹⁹ are not. We expect that aggregation of megakaryocytes by these reagents will show the same species restrictions. Indeed, in our hands, rat megakaryocytes were not aggregated by either ristocetin or bovine plasma. However, botrocetin (venom coagglutinin),^{37,38} a snake venom component from certain *Bothrops* species which, in the presence of vWF, aggregates platelets of all mammalian species examined,³⁹ may aggregate megakaryocytes of other species.

Bovine plasma has several advantages over ristocetin as an agent to aggregate megakaryocytes for subsequent enrichment. First, the megakaryocyte purity achieved was higher with bovine plasma. The lower megakaryocyte purity with ristocetin appeared to result from the formation of some small aggregates of other marrow cells that either adhered to megakaryocytes or sedimented with them. Such aggregates were less frequently observed in megakaryocyte preparations aggregated with bovine plasma. The presence of these other marrow cell aggregates following ristocetin aggregation may be related to the precipitation of plasma proteins by this antibiotic.¹⁷ Second, the use of bovine plasma does not require the addition of another source of vWF, so the system is less complicated. Third, bovine plasma is much less expensive than ristocetin.

In conclusion, megakaryocytes are aggregated by ristocetin and bovine plasma as are platelets. We have used this observation to develop an alternative approach to megakaryocyte enrichment that results in megakaryocyte populations representative of those in unfractionated marrow.

ACKNOWLEDGMENT

We gratefully acknowledge the expert technical assistance of Graydon Nelson for the flow cytometric analyses. The electron microscopy studies were kindly performed in the St. Jude Electron Microscopy facility by Dr Harold Edwards and Donna Davis.

Inhibition of Thromboxane Formation In Vivo and Ex Vivo: Implications for Therapy With Platelet Inhibitory Drugs

By Irene A.G. Reilly and Garret A. FitzGerald

The capacity of platelets to generate thromboxane A_2 , reflected by measurement of serum thromboxane B_2 (TxB_2), greatly exceeds the systemic production of thromboxane in vivo. Thus, it is possible that substantial but incomplete inhibition of thromboxane formation ex vivo would still allow marked augmentation of thromboxane production in vivo. To address this hypothesis, we administered aspirin 120 mg, a selective inhibitor of thromboxane synthase (TxSI), 3-(1H-imidazol-1-yl-methyl)-2-methyl-1H-indole-1-propanoic acid (UK-38,485) 200 mg, and a combination of both drugs to 12 healthy volunteers and measured the effects on serum TxB_2 and urinary 2,3-dinor-thromboxane B_2 (Tx-M), an index of endogenous thromboxane biosynthesis. Although serum TxB_2 was maximally inhibited by $94 \pm 1\%$ after aspirin and $96 \pm 2\%$ after the TxSI, maximal depression of Tx-M was only $28 \pm 8\%$ and $37 \pm 9\%$, respectively. Combination of aspirin with the TxSI resulted in a small but significant increase in inhibition of thromboxane generation ex vivo ($98 \pm 1\%$ v

$94 \pm 1\%$; $P < 0.05$), but a disproportionately greater fall in thromboxane synthesis in vivo ($58 \pm 7\%$; $P < 0.01$). Consistent with further inhibition of platelet thromboxane synthesis, addition of the TxSI abolished the transient decline in prostacyclin formation after aspirin alone. Administration of a lower dose of aspirin (20 mg) to 6 healthy subjects caused a small reduction in Tx-M ($12 \pm 4\%$; $P < 0.05$) and inhibited serum TxB_2 by $48 \pm 2\%$. The relationship between inhibition of platelet capacity to form thromboxane ex vivo (serum TxB_2) and synthesis in vivo (Tx-M) departed markedly from the line of identity. When total blockade of the capacity of platelets to generate thromboxane is approached, minor decrements in capacity result in a disproportionate depression of actual thromboxane biosynthesis. These results imply that pharmacologic inhibition of serum TxB_2 must be virtually complete before thromboxane-dependent platelet activation is influenced in vivo.

THE capacity of tissues to generate eicosanoids in response to physical and chemical stimuli is known to greatly exceed the actual rates of biosynthesis observed in vivo.¹ Formation by human platelets of the potent eicosanoid, thromboxane A_2 , measured as its stable metabolite thromboxane B_2 , is a good example of this phenomenon. Under physiological conditions, the maximal endogenous concentration of thromboxane B_2 in plasma has been estimated to be in the order of 1 to 2 pg/mL.² However, the levels of thromboxane B_2 measured in serum, which reflect the capacity of platelets to form thromboxane in response to thrombin, are over a thousand-fold higher at 300 to 400 ng/mL.³ Thus, the normal rates of thromboxane synthesis observed in vivo can be accounted for by activation of platelets to less than 0.1% of their capacity for thromboxane generation.

The distinction between the capacity for thromboxane production ex vivo and endogenous thromboxane biosynthesis is an important one. In several human syndromes of platelet activation the capacity of platelets to form thromboxane is unchanged, but thromboxane biosynthesis in vivo is increased.^{4,5} Earlier work from our laboratory has suggested that the relationship between the inhibition of the capacity of platelets to generate thromboxane and the persistence of thromboxane-dependent platelet activation may not be linear. An increase in the degree of inhibition of serum thromboxane formation from a mean of 95% to 99% inhibi-

tion, for example, results in a further significant increase in the extent of inhibition of platelet aggregation and a further prolongation of the bleeding time.⁶ In addition, others have shown that even a residual 10% capacity to generate thromboxane is enough to fully sustain thromboxane-dependent platelet aggregation.⁷ These observations have important implications for the use of antiplatelet drugs and inhibitors of the cyclooxygenase and thromboxane synthase enzymes in human syndromes of platelet activation. Many of the clinical and pharmacological studies of platelet inhibitory therapy in such conditions have employed measurement of serum thromboxane B_2 as a guide to the adequacy of dosing.^{8,9} A discrepancy between inhibition of serum thromboxane B_2 and platelet thromboxane production in vivo raises the possibility that despite substantial, but incomplete inhibition of the capacity of platelets for thromboxane generation, actual thromboxane biosynthesis may remain significantly enhanced.

The aim of the present study was to investigate the relationship between inhibition of serum thromboxane generation ex vivo and endogenous thromboxane biosynthesis in order to explore the hypothesis that incomplete inhibition of the capacity of platelets to generate thromboxane allows significant synthesis to continue in vivo.

MATERIALS AND METHODS

Study Design

Twelve healthy male volunteers (aged 21 to 46 years, weight 80.5 ± 5 kg) participated in the study which was approved by the Committee for the Protection of Human Subjects of Vanderbilt University. The main study, which was double blind, randomized, and placebo controlled, was performed on four study days, each separated by a washout period of ten days. On each study day, the volunteers received as a single dose of one of the following: (a) aspirin 120 mg; (b) a thromboxane synthase inhibitor, 3-(1H-imidazole-1-yl-methyl)-2-methyl-1H-indole-propanoic acid¹⁰ (UK-38,485) 200 mg; (c) aspirin 120 mg plus UK-38,485 200 mg, or (d) placebo, each administered as 5 identical unlabelled white capsules

(kindly provided by Dr P. Urquilla of Pfizer Inc., Groton, Conn). All the subjects had fasted for a minimum of ten hours prior to dosing and for four hours after dosing and none had taken aspirin or aspirin-like drugs in the 2-week period prior to or during the study.

Blood was drawn before and 1, 4, 6, 8, and 24 hours after dosing by fresh venipuncture from an antecubital vein for plasma drug levels and serum thromboxane determinations. Urine was collected for measurement of prostacyclin and thromboxane metabolites for the 24 hours before each study day and in 3 postdosing aliquots: 0 to 6, 6 to 12, and 12 to 24 hours. Physical examination, laboratory evaluation, and an EKG were carried out prior to inclusion in the study. Safety tests (full blood count, routine automated biochemistry screen, and urinalysis) were performed before dosing and on completion of each study day. Blood pressure, measured by mercury sphygmomanometer in the sitting position, and heart rate were monitored at each blood sampling time point prior to venipuncture.

On a separate occasion, aspirin was administered to 6 volunteers such as to result in partial inhibition of platelet thromboxane formation *ex vivo*. Four 5 mg aspirin capsules (prepared by the Vanderbilt Pharmacy) were administered two hours apart. Blood was drawn for estimation of serum thromboxane B_2 formation before dosing and eight hours after the first dosage. Urine was collected for eicosanoid analysis for 24 hours prior to dosing and from 0 to 12 and 12 to 24 hours after initiation of dosing.

Finally, blood and urine samples were obtained for measurement of serum thromboxane B_2 and urinary 2,3-dinor-thromboxane B_2 , respectively, from 28 additional apparently healthy volunteers (14 males, 14 females; age 24 to 38 years; wt. 45 to 96 kg) and 4 patients attending the hematology outpatient clinic, two with secondary thrombocytosis, one with hypersplenism, and one with idiopathic thrombocytopenic purpura.

Biochemical Analyses

2,3-dinor-thromboxane B_2 (Tx-M). Tx-M was measured employing a stable isotope dilution assay described in detail elsewhere.¹¹ Briefly, 12.5 ng of a deuterated internal standard was added to a 5 mL aliquot of urine that was then converted to the methoxime derivative by the addition of methoxyamine hydrochloride in acetate buffer. The sample was then applied to a phenylboronic acid column, washed with acid salt followed by methanol, and eluted with 0.1 N sodium hydroxide in methanol. The eluate was acidified, applied to a silica Sep-Pak, washed, and eluted with ethyl acetate. The sample was purified by thin layer chromatography, derivatized to the methoxime, pentafluorobenzyl ester, and further purified by repeat thin-layer chromatography. Derivatization was completed by formation of the trimethylsilyl ether and quantitation accomplished on the Nermag R10-10C operating in the negative ion mode, monitoring m/z 586 for endogenous Tx-M and 590 for the deuterated internal standard.

2,3-dinor-6-keto-PGF_{1 α} (PGI-M). PGI-M was also measured by stable isotope dilution assay employing negative ion-chemical ionization gas chromatography-mass spectrometry as described elsewhere.¹² Briefly, a 5 mL aliquot of urine was first spiked with 5 ng of a deuterated internal standard. The sample was then subjected to extraction and back extraction under alkaline and acidic conditions, and derivatized as the methoxime pentafluorobenzyl ester. Further purification was carried out by thin-layer chromatography and the derivatization completed by formation of the trimethylsilyl ether derivative. Quantitation was accomplished by stable isotope dilution using a Hewlett Packard (Avondale, PA) 5980 instrument operating in the negative ion mode, monitoring m/z 586 for endogenous PGI-M and m/z 590 for the deuterated internal standard.

Serum thromboxane B_2 . Serum thromboxane B_2 generation *ex vivo* was measured as previously described.³ Venous blood was collected into a warmed glass tube, incubated at 37 °C for one hour,

and then spun at 2,000 g for 15 minutes. Serum was separated and stored at -20 °C for later analysis by radioimmunoassay.

Plasma Drug Levels

Plasma concentrations of UK-38,485 were analyzed by high-performance liquid chromatography (HPLC) using UK-37,418 as an internal standard. The drug was isolated from plasma by precipitation with acetonitrile, centrifuged at 2,000 g for five minutes, and evaporated to dryness under nitrogen. After being resuspended in tetramethylethylenediamine (TEMED)/citrate buffer, aliquots were injected onto a Spherisorb Phenyl column (Hichrom, Reading, UK) with a mobile phase of 75% methanol: 25% TEMED/citrate buffer 0.1 mol/L. UK-38,485 and the internal standard were detected by fluorescence at an excitation wavelength of 220 nm and emission of 370 nm. These analyses were kindly undertaken by Dr P. Gibson (Chapel Laboratories, Hythe, Kent, UK) by arrangement with Dr J.F. Faulkner, Pfizer Central Research, Groton, CT. Plasma concentrations of salicylate were measured by a stable isotope dilution assay employing gas chromatography mass spectrometry.¹³

Statistical Analysis

Data were analyzed by nonparametric methods¹⁴ thereby avoiding assumptions as to the distribution of the variables involved. Two-way analysis of variance was by the method of Friedman and subsequent pair-wise analysis was by the Wilcoxon Rank Sum Test. Unless otherwise stated, our results are expressed as the mean $\pm$ the standard error of the mean (SEM).

RESULTS

Platelet Thromboxane Formation

Platelet thromboxane generation *ex vivo* (measured as serum thromboxane B_2) was reduced by $94 \pm 1\%$ one hour after dosing with 120 mg aspirin from 349 ± 37 ng/mL to 18 ± 4 ng/mL. Maximal depression of serum thromboxane B_2 after the thromboxane synthase inhibitor (200 mg UK-38,485) was not significantly different, falling by $96 \pm 2\%$ from 312 ± 33 ng/mL to 12 ± 3 ng/mL one hour after drug administration. While the inhibition induced by aspirin persisted throughout the study period, serum thromboxane B_2 had returned to a mean of 70% of predosing values 24 hours after administration of the thromboxane synthase inhibitor (Fig 1). Combination of aspirin with the synthase inhibitor achieved a minor but significant increase in the degree of inhibition *ex vivo* over that observed with aspirin administration alone: serum thromboxane B_2 fell by $98 \pm 1\%$ from 380 ± 19 to 8 ± 4 ng/mL one hour after dosing. The difference between the combination and aspirin alone, although small, remained statistically significant ($P < 0.05$) one, four, and six hours after drug administration (Fig 1). Serum thromboxane B_2 formation did not change significantly following placebo and there was no significant difference between baseline values on each of the four study days. Administration of the lower dose of aspirin (4×5 mg) resulted in a concomitantly smaller reduction in serum thromboxane B_2 by $48 \pm 2\%$ from 365 ± 21 to 190 ± 8 ng/mL.

Thromboxane Synthesis In Vivo

Peak depression of Tx-M excretion following aspirin 120 mg, which was observed in the six- to 12-hour aliquot after

Fig 1. The effect on platelet cyclooxygenase formation (serum thromboxane B_2) of single dose administration of placebo, UK-38,485 (200 mg), low-dose aspirin (ASA 120 mg), and a combination of low-dose aspirin with UK-38,485 (200 mg) in 12 healthy male subjects. Serum thromboxane is expressed as a percentage of the predosing control value for each treatment regimen. There was no significant difference in serum thromboxane B_2 from control values following placebo administration. Inhibition of serum thromboxane was significantly greater after the aspirin/UK-38,485 combination compared to aspirin alone ($P < 0.05$; one, four, and six hours after dosing) and compared to UK-38,485 ($P < 0.01$; four, six, eight, and 24 hours after dosing). The inhibitory effect of aspirin 120 mg v UK-38,485 (200 mg) on serum thromboxane B_2 was significant only eight and 24 hours after administration ($P < 0.01$).

dosing, was only $28 \pm 8\%$ from predosing values despite almost maximal inhibition of platelet cyclooxygenase throughout the study period (Table 1). The maximal depression of Tx-M excretion after the thromboxane synthase inhibitor was somewhat greater at $37 \pm 9\%$ ($P = 0.06$). Despite the minor increase in inhibition of the capacity of platelets to form thromboxane ex vivo ($94 \pm 1\%$ v $98 \pm 1\%$, $P < 0.05$), addition of the thromboxane synthase inhibitor to the cyclooxygenase inhibitor resulted in a disproportionate fall in thromboxane metabolite excretion ($58 \pm 7\%$) com-

Table 1. Excretion of 2,3-Dinor-Thromboxane B_2 (Tx-M) in 12 Healthy Male Subjects After Single-Dose Administration of Aspirin 120 mg, UK-38,485 200 mg, and Aspirin 120 mg in Combination With UK-38,485 200 mg

Time After Dosing (hr)	Aspirin 120 mg	UK-38,485 200 mg	UK-38,485 200 mg + Aspirin 120 mg
-24	134 ± 21	97 ± 14	95 ± 12
0-6	$108 \pm 18^{\dagger}$	85 ± 10	$65 \pm 9^*$
6-12	$92 \pm 17^{\dagger}$	$56 \pm 6^*$	$47 \pm 11^*$
12-24	$104 \pm 17^{\dagger}$	76 ± 9	$37 \pm 6^*$

Values are expressed in pg/mg creatinine (mean $\pm$ SEM). There were no significant differences between the predosing values.

* $P < 0.01$ compared to control values.

$\dagger P < 0.05$ aspirin 120 mg v aspirin 120 mg + UK-38,485 200 mg.

$\ddagger P < 0.01$ aspirin 120 mg v aspirin 120 mg + UK-38,485 200 mg.

pared to that after aspirin alone ($P < 0.01$). To address the possibility that alterations in Tx-M excretion after aspirin resulted from altered renal tubular handling of the metabolite rather than inhibition of cyclooxygenase¹⁵ we administered an identical (120 mg) dose of sodium salicylate, which is a weak inhibitor of platelet cyclooxygenase compared with aspirin but is subject to the same renal tubular excretory mechanism. In contrast to aspirin 120 mg, sodium salicylate 120 mg did not alter Tx-M excretion or the capacity of platelets to form thromboxane B_2 (Table 2).

Tx-M excretion did not differ significantly prior to drug administration on each of the study days ($P > 0.2$; Table 1). Although there was moderate intersubject variability, the ranges of Tx-M excretion on each of the study days (respectively, 73 to 241, 44 to 167, and 55 to 174 pg/mg creatinine after aspirin 120 mg alone, 200 mg UK-38,485 and the combination of aspirin with UK-38,485) was comparable to that of previous studies by ourselves and others.^{10,11,16} The intrasubject variability was small, with the exception of the two subjects who smoked, a factor that we have subsequently identified as being associated with increased Tx-M excretion.¹⁷ Both of these subjects had higher levels of Tx-M excretion (353 and 363 pg/mg creatinine) during the second (5 mg $\times$ 4 aspirin) study in which smoking had not been restricted. However, the maximum degree of inhibition after aspirin administration was similar whether these subjects were included in the analysis or not: 218 ± 36 falling to 187 ± 52 12 to 24 hours after dosing ($12 \pm 4\%$) v 134 ± 21 falling to 112 ± 22 pg/mg creatinine ($14 \pm 4\%$).

Tx-M excretion was found to be proportional to platelet count over a wide range of platelet counts in apparently healthy subjects (Fig 2). In addition, in two patients with thrombocytopenia due to peripheral platelet destruction and a shortened platelet life span (one with ITP and the other with hypersplenism), Tx-M excretion was correspondingly elevated at 545 and 1600 pg/mg creatinine, respectively (Fig 2). Metabolite excretion was markedly increased in two patients with secondary thrombocytosis. The pattern of recovery of metabolite excretion after reversible (UK-38,485) and irreversible inhibition of platelet cyclooxygenase (Table 1) was also consistent with urinary 2,3-dinor-Tx B_2 principally deriving from platelets.

Table 2. Urinary Excretion of 2,3-Dinor-Thromboxane B_2 (Tx-M), Serum Thromboxane (Tx) B_2 , and Plasma Concentrations of Salicylate in 3 Healthy Male Subjects After Single-Dose Administration of Salicylate 120 mg

	Prior to Dosing	After Dosing	
		Time (hr)	Concentration
Plasma Salicylate (μ g/mL)	ND	3	7.6 ± 1.2
Serum Tx B_2 (ng/mL)	345 ± 75	3	313 ± 29
Tx-M (pg/mg creatinine)	75 ± 13	0-6	85 ± 28
		6-12	78 ± 10
		12-24	72 ± 7

Values are expressed as mean $\pm$ SEM. ND, not detectable; assay sensitivity 10 pg/mL.¹³

Fig 2. The relationship between platelet count and urinary excretion of 2,3-dinor-Tx_B₂ in 32 subjects. Metabolite excretion was discordant with the platelet count in two patients with syndromes associated with an increase in platelet turnover (hypersplenism and idiopathic thrombocytopenic purpura: ITP). When these patients were excluded, the 2,3-dinor-Tx_B₂ excretion significantly correlated ($r = .91$; $P < 0.001$) with platelet count.

Prostacyclin Biosynthesis

Aspirin 120 mg caused a small transient ($25 \pm 11\%$) reduction in PGI-M excretion that was significant in the zero- to 6-hour urine aliquot after dosing ($P < 0.01$). This effect was not apparent when aspirin was administered in combination with the thromboxane synthase inhibitor (Table 3). PGI-M excretion was also unaltered by the lower dose of aspirin (4×5 mg; 120 ± 20 v 128 ± 20 pg/mg creatinine) but was significantly increased ($P < 0.05$) following administration of the thromboxane synthase inhibitor from 119 ± 18 to 143 ± 19 pg/mg creatinine six to 12 hours after dosing (Table 3). There was no significant difference in PGI-M excretion between either the control days that preceded each dosing period or in the three timed aliquots following placebo administration.

Comparison of Inhibition of Thromboxane Formation Ex Vivo and In Vivo

Mean data relating peak inhibition of thromboxane generation ex vivo to peak inhibition of metabolite excretion are

Table 3. Excretion of 2,3-Dinor-6-Keto-PGF_{1 α} (PGI-M) in 12 Healthy Male Subjects After Single-Dose Administration of UK-38,485 (200 mg), Aspirin 120 mg, or UK-38,485 Plus Aspirin 120 mg

Fig 3. The relationship between inhibition of platelet capacity to generate thromboxane (serum thromboxane B₂) ex vivo and thromboxane synthesis in vivo (2,3-dinor-thromboxane (Tx-M) excretion). Data were derived from experiments involving two doses of aspirin (see text), 200 mg of UK-38,485, a thromboxane synthase inhibitor, and a combination of aspirin with the thromboxane synthase inhibitor. Data indicating complete inhibition (0) of both serum thromboxane B₂ (99%) and dinor thromboxane excretion (97%) were obtained after chronic administration of aspirin 2,600 mg/d.⁶

illustrated in Fig 3. Maximum depression of metabolite excretion was measured in the aliquot collected six to 12 hours after dosing with aspirin 120 mg or with UK 38,485, but in the 12- to 24-hour aliquot with the other dosage regimens. The delay in depression of metabolite excretion is likely to reflect a delay both in transformation (as shown thromboxane B₂ infusion²) and in renal clearance.

The relationship between the inhibition of platelet capacity to form thromboxane ex vivo and actual biosynthesis departed markedly from the line of identity. As maximal blockade of the capacity to generate thromboxane ex vivo was approached, minor increments in the degree of inhibition achieved resulted in a disproportionately greater depression of thromboxane synthesis in vivo.

Plasma Drug Levels

Plasma drug levels of UK-38,485 are shown in Table 4. There was no significant difference in the drug concentrations measured whether UK-38,485 was administered either as a single dose or together with 120 mg of aspirin, confirming the absence of any pharmacokinetic interaction between

Table 4. Plasma Concentrations of UK-38,485 (ng/ml)

Treatment Group	Time After Dosing (hr)			
	1	4	6	8
UK-38,485 200 mg	3207 $\pm$ 333	225 $\pm$ 46	66 $\pm$ 8	26 $\pm$ 4
UK-38,485 200 mg plus aspirin 120 mg	2992 $\pm$ 320	199 $\pm$ 22	66 $\pm$ 7	28 $\pm$ 3

Values are expressed as mean $\pm$ SEM in 12 healthy male subjects. Limit of sensitivity 10 ng/mL.

these drugs. Peak drug levels were measured one hour after dosing and the decline in plasma levels following administration of UK-38,485 was rapid, less than 3% of the peak plasma drug levels being detectable after six hours. The temporal discrepancy between the offset in plasma drug levels and the inhibition of serum thromboxane B_2 generation has previously been observed with thromboxane synthase inhibitors and appears to result from supramaximal concentrations of the parent compound at the time of peak drug levels, rather than the presence of active metabolites.¹⁸

DISCUSSION

We have previously established that there is a marked discrepancy between the capacity of platelets to generate thromboxane B_2 and the actual production rate of thromboxane *in vivo*² based on excretion of its urinary metabolite, 2,3-dinor-thromboxane B_2 . If platelets are the major source of this metabolite in urine, this observation suggests that activation of platelets *ex vivo* during blood sampling and processing, rather than endogenous biosynthesis, largely accounts for the plasma levels of thromboxane B_2 widely reported in the literature. The calculated physiological secretion rate of thromboxane B_2 is extremely low, approximately 0.1 ng/kg/min, which would result in a maximal plasma concentration of 1 to 2 pg/mL.² Thus, in healthy individuals in whom minimal evidence of platelet activation *in vivo* would be expected, activation of platelets to less than 0.1% of their capacity would be sufficient to account for these plasma levels.

This concept has implications for therapy with platelet inhibitory drugs in conditions in which platelet activation is of importance. In several human syndromes in which platelet activation *in vivo* has been demonstrated and is thought to play a primary role, endogenous biosynthesis of thromboxane appears to be markedly enhanced.^{4,5,19} For example, urinary 2,3-dinor-TxB₂ excretion is increased on average 4- to 5-fold during episodes of myocardial ischemia in patients with unstable angina.¹⁹ Such increments are of likely pathophysiologic importance in this disease as cardiovascular mortality is significantly reduced by aspirin.²⁰ However, even in the presence of a 95% inhibition of serum thromboxane B_2 , thromboxane biosynthesis could, in theory, be increased 50-fold above basal levels in response to stimuli to its production *in vivo*. Thus, pathophysiologically important increments in thromboxane formation might still occur in patients receiving sufficient aspirin to cause substantial but incomplete inhibition of serum thromboxane B_2 *ex vivo*.

To explore this possibility more directly, we designed the present study to examine the relationship between inhibition of platelet capacity to form thromboxane (serum thromboxane B_2) and inhibition of thromboxane synthesis *in vivo*, as reflected by excretion of its urinary metabolite, 2,3-dinor-thromboxane B_2 . We postulated that as maximal blockade of the capacity to generate thromboxane *ex vivo* was approached, a disproportionately greater inhibition of actual thromboxane synthesis by platelets *in vivo* would be expected. On the basis of previously published work,^{6,21} we selected two doses of aspirin for these studies: the lower dose (5 mg $\times$ 4) was chosen to produce a minor but significant

reduction in *ex vivo* thromboxane formation; and the higher dose (120 mg) as one predicted to cause substantial but incomplete inhibition of thromboxane generation *ex vivo*. In order to inhibit thromboxane formation *ex vivo* still further, we coadministered with aspirin an inhibitor acting as a site distinct from aspirin in the synthetic cascade rather than administering a higher dose of the cyclooxygenase inhibitor. We hypothesized that if such a combined approach resulted in further inhibition of platelet thromboxane synthesis *in vivo*, redirection of platelet endoperoxides, which would accumulate after thromboxane synthase inhibition, might lead to an increase in vascular prostacyclin formation.^{22,23}

We used the excretion of 2,3-dinor-thromboxane B_2 as an index of endogenous thromboxane biosynthesis. This compound has been shown to be the major urinary metabolite of systemically administered thromboxane B_2 in man.²⁴ Several lines of evidence indicate that urinary 2,3-dinor-thromboxane B_2 is largely derived from platelet thromboxane synthesis. First, the pattern of inhibition and recovery of dinor thromboxane after administration of pharmacological inhibitors of thromboxane synthesis is consistent with a predominantly platelet origin of this metabolite. Thus, chronic administration of low-dose aspirin (20 mg daily⁶ and 20 mg twice a day¹⁷) has been shown in two studies in healthy volunteers to cause marked depression of 2,3-dinor-thromboxane excretion, by 85% and 70%, respectively. This occurred in the absence of any significant effect on prostacyclin biosynthesis that provides a marker of extraplatelet cyclooxygenase activity. Similarly, urinary thromboxane B_2 , which, in contrast to the dinor metabolite, is believed to be principally of renal origin under physiologic conditions in humans also remains unaltered following low-dose aspirin administration despite almost maximal inhibition of platelet thromboxane formation *ex vivo*.²⁵ The importance of these observations is that they address the possibility that the platelet represents a source of cyclooxygenase that is extremely sensitive to inhibition by aspirin but that contributes little to the concentration of 2,3-dinor-thromboxane B_2 in urine. Such a phenomenon would explain a discrepancy between the effects of single, low doses of aspirin (eg, 120 ng) on metabolite excretion and serum thromboxane B_2 , such as that illustrated in Fig 3. However, the marked depression of urinary 2,3-dinor-thromboxane B_2 that can be achieved without evidence of inhibition of prostaglandin formation by tissues other than the platelet *in vivo* during chronic administration of low-dose aspirin, renders unlikely such an explanation of our data. Finally, the recovery of dinor thromboxane excretion after irreversible acetylation of platelet cyclooxygenase by aspirin corresponds to platelet life span,^{16,17} while recovery is much more rapid after reversible enzyme inhibition induced by thromboxane synthase inhibitors⁴ or indomethacin.¹⁶ The results reported in this study also show recovery of 2,3-dinor-thromboxane B_2 occurring within 24 hours after the synthase inhibitor, but no recovery during the same observation period after aspirin administration.

A second line of evidence consistent with the platelet being the major source of urinary 2,3-dinor-thromboxane B_2 derives from the measurement of this metabolite in a large number of healthy volunteers as well as in diverse human

syndromes in which platelet activation in vivo has been documented. Over a wide range of platelet counts we have demonstrated a significant correlation between platelet number and dinor metabolite excretion in this study. Of particular interest is the distinction between reduced metabolite excretion in those subjects with a low platelet count as a result of decreased platelet production, and the marked elevation in 2,3-dinor-thromboxane B_2 in the two patients with thrombocytopenia due to increased peripheral destruction of platelets. Enhanced thromboxane synthesis has also been described in association with evidence of platelet activation in vivo in patients with severe peripheral vascular disease,⁴ unstable angina,¹⁹ and systemic sclerosis with Raynaud's phenomenon.⁵ Indeed, that it may be a highly sensitive index of platelet activation in vivo is suggested by the significant elevation is apparently healthy chronic smokers.¹⁷

Finally, inhibition of platelet activation in vivo, using measures that do not directly inhibit the thromboxane biosynthetic pathway, significantly reduces dinor thromboxane excretion. For example, infusion of prostacyclin to patients with thrombotic thrombocytopenic purpura results in a striking reduction in metabolite excretion.²⁶ Consistent with the hypothesis, cessation of smoking is followed by a corresponding reduction in dinor thromboxane.¹⁷ In addition, in patients with severe atherosclerosis and platelet activation in vivo, dietary supplementation with eicosapentaenoate markedly depressed excretion of the dinor metabolite.²⁷

Thus, if the assumption that the platelet is the predominant (although not only) source of the dinor metabolite in urine is valid, a progressive fall in excretion of this metabolite would be likely to reflect progressive inhibition of platelet thromboxane formation in vivo. The results of the present study would then indicate that inhibition of the capacity of platelets to generate thromboxane ex vivo may prove misleading as a guide to the inhibition of actual thromboxane biosynthesis by platelets and hence, thromboxane-dependent platelet activation in vivo. Inhibition of the final 6% of platelet capacity corresponded to inhibition of the final 72% of thromboxane formation in vivo (after aspirin 120 mg). The functional implications of this observation are illustrated by evidence that even a residual 10% capacity to generate thromboxane appears to be enough to fully sustain thromboxane-dependent platelet activation.⁷ Similarly, by increasing the inhibition of platelet thromboxane formation ex vivo from 95% to 99%, an apparently minimal increase, it is possible to achieve further measurable inhibition of platelet

function in normal volunteers, as assessed both by platelet aggregation ex vivo and the bleeding time.⁶ While these observations are not likely to be of clinical importance in healthy individuals, they may be extremely important when stimuli to cause platelet activation are present. The results of the present study indicate that thromboxane biosynthesis may remain markedly enhanced, despite substantial, but incomplete (eg 90%) inhibition of serum thromboxane B_2 .

The changes that we observed in prostacyclin biosynthesis provide further evidence that excretion of 2,3-dinor-thromboxane B_2 in the present study was derived predominantly from platelets. Aspirin 120 mg caused a transient depression in excretion of the prostacyclin metabolite, 2,3-dinor-6-keto-PGF_{1 α} . This is compatible with rapid de novo synthesis of endothelial cyclooxygenase following aspirin exposure, as has previously been shown to occur in cultured endothelial cells.²⁸ However, it contrasts with the more prolonged depression of prostacyclin metabolite excretion observed following chronic administration of much higher doses of aspirin than used in the present study.⁶ Interestingly, such a dose-dependent difference in recovery has also been shown to occur ex vivo in patients who have been receiving aspirin.^{29,30} By contrast, the thromboxane synthase inhibitor resulted in a significant increment in prostacyclin biosynthesis, consistent with utilization of accumulated platelet endoperoxides by vascular prostacyclin synthase.^{22,23,31} Addition of the thromboxane synthase inhibitor abolished the depression of prostacyclin biosynthesis seen when aspirin was administered alone. It is attractive to speculate that this may reflect reorientation of accumulated endoperoxides resulting from additional inhibition of platelet thromboxane formation in vivo, in this case occurring at the level of thromboxane synthase.

Measurements of the platelet capacity to generate thromboxane B_2 ex vivo are frequently employed as a guide to the adequacy of dosing with platelet-inhibitory drugs.³² The results of the present study suggest that biosynthesis of thromboxane is maintained to a substantial degree, unless >95% inhibition of thromboxane generation ex vivo is achieved. Lesser degrees of inhibition would not be expected to substantially influence thromboxane-dependent platelet activation in vivo.

Is Heparin Administration Necessary During Induction Chemotherapy for Patients With Acute Promyelocytic Leukemia?

By Mark A. Goldberg, David Ginsburg, Robert J. Mayer, Richard M. Stone, Maryellen Maguire, David S. Rosenthal, and Joseph H. Antin

The role of heparin in the treatment of the disseminated intravascular coagulation (DIC) associated with acute promyelocytic leukemia (APL) remains unclear. Between 1974 and 1985, we treated 27 patients with APL using four different chemotherapeutic regimens; 23/27 (85%) had evidence of DIC either at presentation or following the initiation of induction chemotherapy. The coagulopathy was treated primarily with fresh frozen plasma and platelet transfusions; only 2/27 (7%) patients received heparin. Twenty of 27 patients (74%) entered complete remission. Major bleeding or thrombotic complications occurred in 5/27 patients (19%), but 2 of these 5 patients presented

after hemorrhage had already occurred. None of the 5 patients with bleeding or thrombosis entered complete remission. All of the hemorrhagic complications due to DIC in our study occurred before 1979, which may reflect changes in the management of leukemic patients. This observation emphasizes the risks inherent in the use of historical controls in this population. In conclusion the DIC associated with APL can be successfully treated with intensive blood product support without the use of heparin.

© 1987 by Grune & Stratton, Inc.

IN contrast to other forms of acute nonlymphocytic leukemia, acute promyelocytic leukemia (APL) is frequently associated with a bleeding diathesis, initially described by Hillestad in 1957.¹ He reported three patients with a rapidly fatal acute leukemia in whom the predominant cell type was an abnormal promyelocyte. All three patients had a severe coagulopathy characterized by thrombocytopenia, hypofibrinogenemia, prolonged bleeding times and thrombin times, and a decreased clot lysis time. While there is some evidence to suggest that the coagulopathy represents primary fibrinolysis,²⁻⁶ it is now generally accepted that the bleeding tendency is primarily the consequence of disseminated intravascular coagulation (DIC) occurring in response to procoagulants released from the abnormal promyelocytic granules.⁵⁻¹¹ As a result, the use of heparin to treat or prevent this form of DIC in patients with APL was introduced by several investigators^{2,12-19} and has become accepted as a standard method of practice,^{20,21} despite the absence of a prospective randomized trial documenting its efficacy. We have been reluctant to administer heparin to thrombocytopenic, critically ill patients without unequivocal demonstration of its value. Consequently, during the past 11 years the majority of our patients (25/27) with APL have been managed with intensive fresh frozen plasma (FFP) and platelet support, and intensive chemotherapy without the concomitant use of heparin. The results of our experience and a review of the literature comprise this report.

METHODS

We retrospectively reviewed all cases of acute myelogenous leukemia diagnosed and treated at the Brigham and Women's Hospital and the Dana-Farber Cancer Institute between January 1974 and June 1985. During this period, 27/371 (7%) patients fulfilled the morphologic criteria of the French-American-British (FAB) classification²² for hypergranular APL (FAB M3 histologic subtype). Since 1981 cytogenetic studies were performed in the Dana-Farber Cancer Institute cytogenetics laboratory. The 27 patients were treated with various remission induction chemotherapy regimens, all of which contained cytosine arabinoside and an anthracycline (Table 1) as described previously.²³⁻²⁵

Complete remission (CR) was defined according to CALGB criteria as less than 5% blasts on bone marrow aspiration with evidence of maturation of all bone marrow cell lines and restoration of peripheral blood counts.²⁶ The diagnosis of DIC in this leukemic

population was defined as the presence of any two of the following abnormalities: (1) prothrombin time (PT) 3 or more seconds greater than control, (2) activated partial thromboplastin time (aPTT) 5 or more seconds greater than the upper limit of the normal range, (3) thrombin time (TT) prolonged by 3 or more seconds compared to control, (4) fibrinogen less than 150 mg/dL, and (5) fibrin degradation products (FDP) greater than or equal to 40 µg/mL. Survival was calculated from the date of diagnosis and was assessed by the life table analysis described by Peto et al.²⁷ The Mantel-Haenszel test was used to compare differences between different cohorts.²⁸

Coagulation parameters and complete blood counts were obtained at least once daily. All patients with thrombocytopenia, anemia, evidence of DIC, or clinical bleeding were treated with platelet and red blood cell transfusions and fresh frozen plasma. In general, in the absence of bleeding, platelet transfusions were administered when the platelet count fell to 20,000/µL or less and fresh frozen plasma (2 to 4 U/d) was given to maintain a plasma fibrinogen concentration of approximately 150 mg/dL or to correct the prothrombin time to less than 3 seconds beyond control. Heparin was neither routinely used for the treatment of DIC nor was it given prophylactically. Any decision concerning the initiation of heparin treatment in patients with laboratory evidence of DIC was left to the discretion of the responsible physician. Induction chemotherapy was begun within 48 hours after diagnosis, even if DIC were present.

RESULTS

Patient characteristics. The characteristics of the 27 patients with APL are summarized in Table 2. The median

age was 37; there were 14 males and 13 females. Generally, patients were severely thrombocytopenic and anemic. As previously reported,⁸ leukopenia was commonly observed; the median white blood cell (WBC) was 1,850/mm³. Cytogenetic studies were performed on marrow specimens from 8 patients; 6 of these 8 had the 15:17 translocations that are characteristic of APL.²⁹ No other cytogenetic abnormalities were observed. Twenty-three of the 27 (85%) patients had DIC at diagnosis or developed DIC with institution of chemotherapy but only 2 of the 27 patients received heparin. The incidence of specific coagulation abnormalities is detailed in Table 2.

Treatment of coagulopathy. In order to determine the transfusion requirements of patients with DIC who were not treated with heparin, we analyzed the records of the group of patients who were treated without heparin on the VAPA and DAC II protocols (since after 1979 there was more uniform availability of platelet concentrates in our institutions).

Heparin, FFP, and platelets	2
Platelets and/or FFP	25

*Percentage of patients with DIC who demonstrated the abnormal coagulation test is shown in parentheses. The definition of abnormal values is described in Methods.

†Data was only available on 22 patients with DIC.

Fifteen of these 18 patients met our criteria for DIC, and we have complete transfusion records on 14 of the 15. The median duration of DIC as defined above was four days (range one to ten days). The FDPs were elevated (≥ 40 μ g/mL) for a median of six days (range zero to ten days), while the plasma fibrinogen was <150 mg/dL for a median duration of four days (range one to ten days). Fresh frozen plasma was often administered at times when patients did not meet our strict criteria for DIC but had elevated FDPs or low fibrinogens. Consequently we divided the total number of units of FFP and platelets administered per patient by the duration of DIC or seven days, whichever was longer. That number provides an estimate of the daily blood product requirements during the period of highest risk for the development of DIC. The patients received a median number of 1.9 units of FFP/d (range 0.3 to 6.3 U/d) and 6 units of platelets/d (range 0 to 11 U/d). The coagulation parameters and response to therapy of a representative patient is shown in Fig 1.

Hemorrhagic and thrombotic complications. Five of the 27 patients (19%) had major bleeding or thrombotic complications. Two of these 5 patients had intracranial hemorrhages and were moribund when we first evaluated them, while 2 additional patients developed intracranial hemorrhages while receiving induction chemotherapy. It was noteworthy that only 4 patients had prolonged activated partial thromboplastin times and 3 of these 4 died of intracranial hemorrhage. Hepatic vein thrombosis and pulmonary hemorrhage occurred in the fifth patient during the second course of induction therapy. However, postmortem examination

Fig 1. Response to therapy of a representative patient. This patient had abnormalities of all five coagulation parameters at diagnosis. Institution of chemotherapy and blood product support resulted in rapid amelioration of the DIC. Each arrow indicating a platelet transfusion represents 6 to 10 units of platelets.

revealed hepatic venoocclusive disease (VOD) without laboratory or pathologic evidence of DIC.

Remission and survival data Twenty of the 27 patients (74%) entered CR. The median follow-up of the group was 503 days (range 1 to 2706 days) and the probability of survival at 3 years was $38 \pm 11\%$ (Fig 2). If the patients who achieved a complete remission were examined separately, the median follow-up was 632 days (range 151 to 2706 days) and the probability of survival at 3 years was $51 \pm 13\%$ (Fig 2).

DISCUSSION

The etiology of the hemorrhagic diathesis associated with APL has been the subject of much study. Several investigators have demonstrated an increased rate of fibrinogen catabolism in patients with APL.³⁰⁻³³ However, the relative contributions of primary fibrinolysis and DIC to the coagulopathy of APL are controversial. In a review of the literature, Groopman and Ellman⁸ found that measurements of plasminogen and plasmin levels, as well as clot lysis and euglobulin lysis times yielded variable results and generally had not provided convincing evidence of systemic fibrinolysis. Evidence in support of primary fibrinolysis includes the report by Keene et al³ of three patients with APL treated with epsilon-amino caproic acid (EACA). Although the bleeding in these patients ceased and they all entered CR, the absence of detailed data concerning coagulation studies makes the contribution of EACA difficult to interpret. Bennett et al⁴ also proposed a role for primary fibrinolysis in the hemorrhagic diathesis seen in APL based on their observation that transfused ⁵¹Cr-labeled autologous platelets had a normal life span in a patient with APL while the half life of ¹²⁵I-labeled fibrinogen was markedly decreased.

Several lines of investigation have pointed to a major role for DIC in the coagulopathy of APL. In 1973, Gralnick and Abrell⁵ demonstrated significant procoagulant properties associated with the lysates of leukocytes obtained from patients with APL. The procoagulant activity was further localized to the granular fraction of these leukocytes and was not present in granular fractions obtained from normal controls or patients with other forms of acute nonlymphocytic leukemia. They also demonstrated a less marked, but significant increase in fibrinolytic activity present in the granular fraction in 3 of 4 patients with APL. Furthermore, a response to heparin with normalization of clotting parameters and clinical cessation of bleeding suggested that DIC played a predominant role in the bleeding diathesis of APL.¹² Bauer and Rosenberg¹¹ provided direct evidence that patients with APL generate excessive amounts of thrombin within the vascular system. They employed sensitive radioimmunoassays to study the levels of prothrombin activation fragment, F_{1+2} , thrombin-antithrombin complex (TAT), and fibrinopeptide A (FPA) in patients with APL undergoing intensive chemotherapy. They showed an excellent correlation between elevations in F_{1+2} , TAT, and FPA. Finally, postmortem findings consistent with DIC in patients with APL have been frequently reported.^{9,10,12,34}

Baker et al³⁵ first reported the use of heparin in 1964 in the treatment of a hemorrhagic diathesis in a patient with AML who had 24% promyelocytes with some atypical forms in his

Fig 2. Life table analysis of overall survival of patients with APL; All patients (solid line), and all patients who achieved a complete remission (interrupted line). The bars indicate the standard error at 3 years. Tic marks indicate patients who are currently alive.

bone marrow aspirate. The patient had gross clinical bleeding unresponsive to EACA. Initially low levels of fibrinogen, factor V, and plasminogen all increased after institution of heparin therapy. However, the patient subsequently died and postmortem examination showed findings consistent with widespread DIC and leukemic infiltration. In 1972, Gralnick et al¹² reported four patients with APL and DIC, of whom three were treated with heparin and one with platelet transfusions, fresh frozen plasma, and fibrinogen. All four patients died; autopsy revealed that 3 of the 4 had persistent leukemia and all had evidence of thrombosis and/or hemorrhage. However, the three patients treated with heparin did have a marked improvement in coagulation abnormalities associated with decreases in clinical bleeding.

The goal of heparinization in patients with APL is to inhibit DIC by stopping the accelerated fibrin formation and associated secondary fibrinolysis. To examine the kinetics of fibrin formation in such patients, Bauer and Rosenberg¹¹ measured the formation of FPA in patients receiving heparin. The only patient to have a significant reduction in FPA production received 1,000 u/m²/hr of heparin. This patient also had a doubling of the aPTT while receiving heparin. Hence, both normal as well as pathologic coagulation may have been inhibited. Clearly, in a patient with a platelet count in the range of 20,000/mm³, heparinization is not without significant risks.

The coagulopathy commonly observed in patients with APL at the time of diagnosis is thought to reach its maximal intensity shortly after the initiation of chemotherapy at which time the destruction of leukemic cells results in the release of procoagulant-rich granules. Once significant cytoreduction has been achieved, the stimulus for the coagulopathy diminishes and clotting parameters return to normal. Therefore, our efforts in addressing the DIC associated with APL have focused on the rapid removal of the cause of DIC (ie, the abnormal promyelocytes) by the prompt initiation of chemotherapy. We support such patients with judicious platelet and fresh frozen plasma transfusions until the DIC has resolved (Fig 1). Our patients received doses of FFP and platelets which are easily obtained by most blood banks. Heparin was used in the management of only 2 (7%) of our 27 patients with no patients being so treated during the last 4

years. Our overall complete remission rate of 74% compares favorably with results reported by others, both in studies in which heparin was and was not used (Table 3). There were 4 (15%) hemorrhagic deaths in our patient cohort, all of which were due to intracranial hemorrhage; 2 of these 4 hemorrhagic deaths could not have been prevented with heparin since the patients presented with major intracranial catastrophes at the time of their diagnoses. Although the aPTT was the least sensitive measure of the presence of DIC in this patient population, elevations of the aPTT at presentation appeared to be associated with severe hemorrhagic complications. Three of the 4 patients who had prolonged aPTT's died of intracranial hemorrhage. While the number of patients is too small for reliable statistical inferences, perhaps patients with a prolonged aPTT reflect a subgroup with a worse prognosis.

The impact of heparin on the management of patients with APL remains unclear. A compilation of reported series of patients with APL reveals no statistically significant benefit for the use of the anticoagulant with a 19% incidence of hemorrhagic deaths being associated with the use of heparin compared to a 28% death rate without heparin ($P > 0.05$, Table 4). The complete remission rate of these combined series using heparin was 63% in contrast to 54% without heparin ($P > 0.1$, Table 3). It is noteworthy that the majority of patients comprising the "nonheparin" group were treated more than 10 years ago. Seventeen (85%) of the 20 patients we have treated during the past 6 years have entered complete remission without any hemorrhagic deaths. This higher probability of remission is consistent with the generally accepted improved response rate observed in patients with acute nonlymphocytic leukemia during the last decade.³⁷ Such an improvement may be attributable not only to more intensive chemotherapeutic regimens, but also to the increased availability of blood product support and improvements in antimicrobial agents. The introduction of prophylactic heparin therapy into APL induction regimens temporally corresponded to these advances in care. Since the

apparent benefit of such anticoagulation was only appreciated by a comparison with historical experience, it is possible that the more recently observed improvement in outcome is in fact due to these other advances in care and not due to heparin therapy. Finally, in all recently published studies in which heparin has been used, patients were concomitantly treated with platelet concentrates, at times in association with fresh frozen plasma. Such platelet concentrates are known to contain significant amounts of coagulation factors.³⁸ Therefore, it is conceivable that much of the improvement in clotting parameters and control of clinical bleeding observed in patients with APL who were given heparin might actually have been the result of the simultaneous administration of platelet concentrates and fresh frozen plasma.

We conclude that the coagulopathy associated with APL can be successfully managed with intensive chemotherapy and blood product support without the routine use of heparin. The necessity for the inclusion of prophylactic heparin therapy into the remission induction regimens of all patients with APL has not been proven, and the impact of such anticoagulant therapy remains unclear. To clarify the relative values of fresh frozen plasma and platelet transfusion and heparin prophylaxis, a prospective randomized trial would be required.

Thrombocytopoietic Response to Immunothrombocytopenia in Nude Mice

By Shirley Ebbe, Jack Levin, Kathleen Miller, Tamlyn Yee, Francine Levin, and Elizabeth Phalen

Thrombocytopoiesis was evaluated in T cell-deficient nu/nu mice and in T cell-replete nu/+ controls to determine if abnormalities would be associated with the deficiency of T cells. Mice were studied in the unperturbed steady state and after acute immunothrombocytopenia was induced by an injection of guinea pig antmouse platelet serum (APS). The state of thrombocytopoiesis was determined from platelet counts, megakaryocyte size, megakaryocyte number, and numbers of Meg-CFC. Splenic lymphocytes were evaluated by responses to the mitogens bacterial lipopolysaccharide (LPS), phytohemagglutinin (PHA), and concanavalin A (Con A). Hematocrits, reticulocyte counts, leukocyte counts, marrow cellularity, GM-CFC, and BFU-E also were measured. Steady state thrombocytopoiesis was identical in nu/nu and nu/+ mice. In response to an injection of APS, acute thrombocytopenia was followed by macromegakaryocytosis and rebound thrombocytosis in mice of both genotypes. Splenic Meg-CFC increased in nude mice after APS or an injection of normal guinea pig

serum (NGpS), and splenic GM-CFC increased after APS. Neither Meg-CFC nor GM-CFC increased in the spleens of nu/+ mice, but they showed early transient increases in bone marrow that did not occur in nu/nu mice. Sporadic, but weak, mitogenic responses to PHA or Con A were occasionally observed with nu/nu spleen cells, but these did not correlate with the state of thrombocytopoiesis. The results demonstrated that platelet production was normal in nu/nu mice and that megakaryocytopoiesis and platelet production responded to the stimulus imposed by acute immunothrombocytopenia. Increases in megakaryocyte size and platelet production occurred independently of changes in numbers of Meg-CFC, GM-CFC, or BFU-E. A normal complement of T cells appears to be unnecessary for normal platelet production and its augmentation in response to the stimulus of acute immunothrombocytopenia in vivo.

This is a US Government work. There are no restrictions on its use.

THE rate of platelet production is appropriately adjusted in response to experimental perturbations of the platelet count. Therefore, it can be concluded that thrombocytopoiesis is regulated. Several levels of platelet precursors have been shown to respond to the stimulation of thrombocytopoiesis that is produced in experimental animals by injection of heterologous antiplatelet serum (APS) to induce thrombocytopenia. Alterations of recognizable megakaryocytes and their immediate precursor cells tend to occur promptly after induction of thrombocytopenia,¹⁻³ but responses of less differentiated cells, such as megakaryocyte colony-forming cells (Meg-CFC), are generally relatively delayed.⁴⁻⁶ The observations are consistent with multiple levels of megakaryocytic regulation in which more mature cells respond to a platelet-dependent regulatory mechanism, ie, thrombopoietin, and less mature cells respond to other, as yet unidentified, mechanisms.⁷ However, cellular interactions

that may be responsible for control of thrombopoietin production or mediation of other thrombocytopoietic regulatory functions have not been identified.

Dual regulation also has been proposed for growth of Meg-CFC in vitro.⁸ Both a colony-stimulating factor that promotes cell proliferation and a potentiator for maturation have been reported to be necessary.⁸ However, growth of megakaryocyte colonies, as well as cells that form colonies of other types of hematopoietic cells, can also be induced by the conditioned medium that is produced by spleen cells when they are exposed to a T cell mitogen, and this medium appears to contain all growth factors necessary for proliferation and maturation of megakaryocytes in vitro.^{9,10} Because of the potent effect of T cell products on Meg-CFC in vitro and the occasionally associated occurrence of platelet and immunological abnormalities in vivo, it has been proposed that T cells may play a thrombocytopoietic regulatory role in vivo.^{11,12} The possibility also has been suggested that immunothrombocytopenia, induced by APS, might result in changes in Meg-CFC that were more dependent on immunological stimulation of T cells than on the thrombocytopenia per se.¹³

The present experiments were based on the concept that if T cells are important for the regulation of platelet production or for some aspects of the responses to APS, abnormalities of thrombocytopoiesis or its response to immunothrombocytopenia might be found in T cell-deficient nude (nu/nu) mice. Athymic mice have been reported to have normal platelet and megakaryocyte counts,¹⁴ but their ability to increase platelet production in response to stimulation has not been reported.

MATERIALS AND METHODS

Mice. Athymic nude (nu/nu) mice were studied, and heterozygous hirsute nu/+ mice were used as controls. Mice were obtained from Charles River Breeding Laboratories (Wilmington, Mass) and from NCI-Frederick Cancer Research Facility (Frederick, Md). Nu/nu mice were housed, 5/cage, in a protective environment (Airo Clean Engineering Inc., Broomall, Pa); nu/+ mice were kept in a

standard mouse room. At the time of study, the mice were about 12 weeks old; each mouse was anesthetized with ether, a sample of cardiac blood was drawn, and the mouse was killed by cervical dislocation.

Blood and bone marrow cell counts. The cardiac blood samples were anticoagulated with dry K_2EDTA . Platelet counts were done by phase microscopy.¹⁵ Microhematocrits were determined with a Drummond centrifuge (Drummond Scientific, Broomall, Pa). Reticulocytes were counted by microscopy after staining with new methylene blue.¹⁶ Leukocytes were counted with a Coulter counter (Coulter Electronics Inc., Hialeah, Fla) at a 1:500 dilution in Isoton and Zapoglobin (Coulter).

Bone marrow was flushed from each tibia with 1 mL of 1% Na_2EDTA in saline. Total cells were counted by Coulter counter at a 1:500 dilution in Isoton and Zapoglobin. Megakaryocytes were counted by microscopy with a hemacytometer, after addition of 0.1 volume of new methylene blue; duplicate counts were done on each tibia, and the average number for both tibiae was calculated.

Megakaryocyte size. Smears of bone marrow were made from split femurs with a 000 paint brush and then stained with Wright's and Giemsa stains. Stage III megakaryocytes were identified by microscopy based on the morphological characteristics of azurophilic granules throughout the cytoplasm and low nucleus:cytoplasm ratio. Areas of stage III cells that had intact cytoplasmic borders were measured microscopically with a Zeiss MOP-3 digital image analysis system (Carl Zeiss, Oberkochen, W. Germany). Sizes were recorded as "units"; each unit was equal to 1 mm^2 of the measuring tablet. A stage micrometer with divisions equal to 10μ was used to determine that the linear magnification was $1230\times$. Based on a circular shape for the cells (a reasonable approximation for most megakaryocytes) 1000 "units" corresponded to an area of $660\mu^2$ in the bone marrow smear. Areas of 50 megakaryocytes were measured for each mouse, and the average area was calculated. This average was then used to calculate average areas for each treatment group; that is, each mouse was represented in the final calculations by one number, not 50 numbers.

Guinea pig sera. Blood was collected, by cardiac puncture, from untreated guinea pigs under ether anesthesia. After it clotted, normal guinea pig serum (NGpS) was prepared by centrifugation and stored at -20°C . It was diluted 1:4 with saline, and 0.1 mL was injected intraperitoneally into each mouse treated with NGpS.

Guinea pig antimouse platelet serum (APS) was prepared by injection of guinea pigs with mouse platelets ($\sim 3 \times 10^9$ platelets/injection) suspended in complete Freund's adjuvant (Difco Laboratories, Detroit, Mich) and saline. The first injection was given into the foot pads and subcutaneously; 3 subsequent injections were given subcutaneously at 1, 2, and 4 weeks after the first. Immune serum was collected from cardiac blood 1 week after the final injection, and stored at -20°C . Prior to use, it was heated to 56°C for 30 minutes, absorbed 3 times with equal volumes of washed mouse red cells, and then again stored at -20°C . It was diluted 1:4 with saline, and 0.1 mL was injected intraperitoneally into each mouse treated with APS.

Megakaryocyte and granulocyte-macrophage colony-forming cells (Meg-CFC and GM-CFC). Single-cell suspensions were prepared from bone marrow and spleen as previously described.^{4,17} All cultures were performed in 35 mm diameter plastic Petri dishes (Falcon Laboratories, Oxnard, Calif) using a 0.3% agar medium which contained Dulbecco's modified Eagle's medium and 20% horse serum (Flow Laboratories, Inc., McLean, Va), prepared according to a modification of the method of Metcalf et al.⁹ To each culture dish, 0.1 mL of pokeweed mitogen-stimulated spleen-conditioned medium was added. Bone marrow cultures contained 25,000 or 50,000 cells/mL, and spleen cell cultures contained 0.5×10^6 or 1.0×10^6 cells/mL.

After seven days of incubation at 37°C in 100% humidity and 10% CO_2 in air, cultures were scored for colonies using an Olympus dissecting microscope (Olympus Corp., Lake Success, NY) with indirect lighting and $\times 35$ to 40 magnification. Aggregates of 50 or more cells were scored as colonies except for megakaryocytes, for which 3 or more cells were considered a colony. Data presented in this article were based on triplicate cultures of cells pooled from 2 mice for each experimental point in each experiment. Granulocyte-macrophage (GM) colonies and megakaryocyte (Meg) colonies were enumerated, based on their morphological characteristics. The number of Meg colonies was confirmed by drying the agar cultures in situ with a hot plate and hair drier, followed by staining of the dried cultures for acetylcholinesterase, as described previously.^{4,17} Colonies were considered megakaryocytic if at least 3 cells demonstrated the characteristic orange-brown color, indicative of acetylcholinesterase, in the cytoplasm. The total numbers of Meg-CFC and GM-CFC per organ (femur or spleen) were calculated from their respective frequencies in cultures and the total nucleated cell count per femur or spleen.

Erythroid burst-forming unit (BFU-E). Humeral bone marrow suspensions were prepared in RPMI 1640 (Gibco Laboratories, Santa Clara, Calif) supplemented with $50\mu\text{g/mL}$ gentamycin sulfate (Schering Corp, Kenilworth, NJ). Marrow was flushed from the bone using a 22 gauge needle, and single-cell suspensions were prepared by gently passing the cells through a 27 gauge needle. Cells were counted using a hemacytometer, and viability was determined by eosin exclusion. BFU-E were cultured in methylcellulose using a modification of the method of Stewart et al.¹⁸ The culture medium consisted of 0.8% methylcellulose (Dow Chemical, Walnut Creek, Calif), 1 mmol/L L-glutamine (Gibco), 10^{-4} mol/L mercaptoethanol (Sigma Chemical Co., St. Louis, Mo), $28\mu\text{g/mL}$ CaCl_2 (Sigma), 1% BSA (Fraction V, Miles Scientific, Naperville, Ill) which had been deionized and lyophilized according to the method of McLeod et al.,¹⁹ 30% fetal bovine serum (FBS; Flow), and alpha MEM (Gibco) containing $50\mu\text{g/mL}$ gentamycin sulfate (Schering). Human urinary erythropoietin (4.78 U/mg; kindly supplied by Dr Gisela Clemons) was added at a final concentration of 2.5 U/mL. Bone marrow cells were plated at a concentration of 2×10^5 cells/mL. Cultures were incubated at 37°C in 5% CO_2 in air with saturated humidity. Bursts were scored in unstained cultures after seven days using an inverted microscope at $40\times$ magnification. Erythroid bursts were identified by the presence of hemoglobin which gave a pink-orange-red color to the cells and by their colony morphology and individual cell size. Colonies with multiple large aggregates that contained >50 cells (usually >100) were scored as BFU-E. Data are presented as mean number of BFU-E $\pm$ SEM for at least 6 cultures of pooled marrow from 3 mice/group.

Mitogen assays. Spleen cell suspensions were prepared in RPMI 1640 (Gibco) supplemented with $50\mu\text{g/mL}$ gentamycin sulfate (Schering). Cell suspensions were made by teasing cells loose from the capsule with an 18 gauge needle. Single-cell suspensions were made by passing the cells several times through the tip of a Pasteur pipette followed by passage through a fine mesh nylon sock to remove the large clumps. The cells were counted using a hemacytometer, and viability was determined by eosin exclusion. Spleen cells were cultured in RPMI 1640 (Gibco) that contained 5% FBS (HyClone Laboratories, Logan Ut; a lot screened for low background response), 1 mmol/L sodium pyruvate (Gibco), 1% nonessential amino acids (Gibco), $50\mu\text{g/mL}$ gentamycin sulfate (Schering), and $5 \times 10^{-5}\text{ mol/L}$ mercaptoethanol (Sigma). Cells were cultured in quadruplicate in 96 well microtitre plates (Falcon) in a total volume of 0.2 mL/well containing 5×10^5 spleen cells and $2.5\mu\text{g/mL}$ phytohemagglutinin (PHA, Difco), $2.5\mu\text{g/mL}$ concanavalin A (Con A) (Miles), or $25\mu\text{g/mL}$ lipopolysaccharide (LPS; Difco). Cultures were incubated at 37°C in a humidified atmosphere.

containing 5% CO₂. After 48 hours, 1 microcurie of tritiated thymidine (³HTdR; New England Nuclear, Boston, Mass) was added to each well; 16 hours later the cultures were harvested and cell radioactivity determined. Samples were harvested onto glass fibre filters using an automated sample harvester (Dynatech Laboratories, Inc., Alexandria, Va), and incorporated radioactivity was measured using a liquid scintillation counter (Beckman Instruments, Inc., Fullerton, Calif). The results are expressed as the mean counts per minute (cpm) of quadruplicate microwells $\pm$ SEM.

Statistical analysis. The significance of differences between mean values for different groups was determined with Student's *t* test. Only cases with *P* < 0.05 are reported as significantly different.

RESULTS

In the present experiments, two approaches were utilized to determine if regulation of thrombocytopoiesis was normal or abnormal in *nu/nu* mice. The first was to compare hematological data in untreated *nu/nu* mice with those of untreated *nu/+* controls. The second was to compare the responses of the two genotypes to acute thrombocytopenia produced by a single injection of APS.

Blood and marrow findings in untreated *nu/nu* and *nu/+* mice are presented in Table 1. Platelet counts, numbers of tibial megakaryocytes, sizes of mature megakaryocytes, and leukocyte counts were identical in both. The average hematocrit was slightly, but significantly, lower in *nu/nu* than in *nu/+* mice, but reticulocyte percentages were the same. Total tibial cellularity was lower in *nu/nu* than in *nu/+*.

Figure 1 shows data that confirm the T cell-deficient state of spleen cells from untreated nude mice. Spleen cells from *nu/+*, but not those from *nu/nu*, mice were stimulated to incorporate ³HTdR by incubation with the T cell mitogens PHA or Con A. Spleen cells from both genotypes responded equally to the B cell mitogen LPS.

Figure 2 shows blood platelet counts after an injection of APS, NGpS, or saline. Severe thrombocytopenia was present four hours after APS. Extensive cutaneous petechiae were visible on the hairless *nu/nu* mice. The subsequent recovery of platelet counts was similar in both genotypes. Significant rebound thrombocytosis occurred on days 5 and 6 with platelet counts of 146% to 193% of controls injected with NGpS. Day 6 platelet counts were significantly higher in

Fig 1. Tritiated thymidine incorporation into 5×10^5 spleen cells from untreated *nu/nu* and *nu/+* mice, assayed after culture in medium alone (background) or in the presence of a mitogen. Each point represents the mean counts per minute (cpm) for quadruplicate cultures.

nu/nu than *nu/+* mice injected with APS, but both genotypes showed thrombocytosis relative to controls injected with NGpS.

Average sizes of stage III megakaryocytes after an injection of APS, NGpS, or saline are presented in Fig 3. There was an abrupt increase in size on day 2 after APS to 141% to 161% of the size in controls injected with NGpS, after which sizes returned to normal.

Fig 2. Platelet counts of (A) *nu/nu* and (B) *nu/+* mice after a single injection of APS, NGpS, or saline given at time zero. Values for APS and NGpS are the mean $\pm$ 1 SEM for 4 to 14 mice. Values for saline represent 3 to 4 mice. Platelet counts of *nu/nu* and *nu/+* mice injected with APS were significantly greater than controls injected with NGpS on days 5 and 6. On day 6, platelet counts of *nu/nu* mice injected with APS were higher than those of APS injected *nu/+* mice.

‡Stage III megakaryocytes.

§Mean $\pm$ 1 SEM.

Fig 3. Areas of stage III megakaryocytes of (A) *nu/nu* and (B) *nu/+* mice after a single injection of APS, NGpS, or saline given at time zero. Values for APS and NGpS are the mean $\pm$ 1 SEM for 4 to 12 mice; individual values for saline treated mice are shown. Mean size for both genotypes was significantly ($P < 0.001$) greater after APS than after NGpS on day 2. 1,000 units of size, as plotted here, is equivalent to an unmagnified area of about $660 \mu^2$.

Hematocrits and leukocyte counts showed no differences between mice injected with APS and those injected with NGpS; reticulocyte counts were significantly higher (2.1 ± 0.2 [SEM] ν $1.1 \pm 0.3\%$) on one occasion, day 4 in *nu/+* mice. In the marrow, *nu/+* mice had significantly more megakaryocytes after APS than NGpS on day 2 ($13.4 \pm 2.1 \nu 8.4 \pm 0.8 \times 10^3$ /tibia), and slight hypercellularity was found on day 6 (*nu/nu*: $11.2 \pm 0.6 \nu 9.3 \pm 0.6 \times 10^6$ cells/tibia; *nu/+*: $11.7 \pm 0.8 \nu 9.1 \pm 0.6 \times 10^6$ cells/tibia).

Numbers of splenic Meg-CFC and GM-CFC are illustrated in Fig 4. Both types of colony-forming cells increased in the spleens of *nu/nu* mice after an injection of APS (Fig 4A and 4B), but only Meg-CFC increased after an injection of NGpS (Fig 4A). In contrast, neither type of colony-

Fig 4. Total splenic Meg-CFC (panels A and C) and GM-CFC (panels B and D) after injection of APS or NGpS; controls were injected with saline. Meg-CFC were significantly ($P < 0.05$) greater than control in *nu/nu* mice (panel A) on day 4 after NGpS and on day 5 after APS. GM-CFC were significantly ($P < 0.05$) greater than control in *nu/nu* mice (panel B) on days 2, 4, 5, and 6 after APS. Other values did not differ from control values. Each point shows the mean and SEM of 3 experiments. The dashed line represents the mean $\pm$ 1 SEM of 10 control mice of the appropriate strain.

forming cell increased in the spleens of *nu/+* mice after injection of APS or NGpS (Fig 4C and 4D). Figure 5 summarizes numbers of bone marrow Meg-CFC, GM-CFC, and BFU-E. None of these cell types increased in the marrow of *nu/nu* mice after injection of APS or NGpS (Fig 5A, 5B, and 5C). Control *nu/+* mice showed an increase in Meg-CFC and GM-CFC four hours after APS (Fig 5D and 5E) and in Meg-CFC four hours after NGpS (Fig 5D); BFU-E did not increase (Fig 5F).

To explore the possibility that the injections of heterologous sera might have recruited latent T cell function in *nu/nu* mice, serial responsiveness of spleen cells to mitogens was determined after the injection of APS or NGpS. The results after APS are presented in Fig 6. As in the untreated mice shown in Fig 1, B cell function, ie, mitogenic response to LPS, was initially intact in *nu/nu* mice, but tended to diminish on days 5 and 6. Incorporation of $^3\text{HTdR}$ into *nu/nu* spleen cells after incubation with PHA or Con A did not exceed the baseline levels observed when cells were incubated in medium alone, except for a weak response to Con A on day 6. Responses to all mitogens were intact throughout the experiment in *nu/+* spleen cells. The results after injection of NGpS are shown in Fig 7. Responses to LPS were intact in both genotypes throughout the experiment as were responses to PHA and Con A in *nu/+* mice. Weak T cell responses were seen in *nu/nu* mice at six days to PHA and Con A and at four hours to Con A.

DISCUSSION

In the present experiments, untreated T cell-deficient *nu/nu* mice were found to be identical to T cell-replete *nu/+* controls with respect to platelet count, megakaryocyte number, and megakaryocyte size. Furthermore, both geno-

Fig 5. Total femoral Meg-CFC (panels A and D), femoral GM-CFC (panels B and E), and humeral BFU-E (panels C and F) after injection of APS or NGpS; controls for Meg-CFC and GM-CFC received an injection of saline; controls for BFU-E were untreated. The dashed line represents the mean $\pm$ 1 SEM of 10 control mice of the appropriate strain.

Fig 6. Serial observations of tritiated thymidine incorporation into 5×10^5 spleen cells from nu/nu and nu/+ mice after injection of APS. Assays were performed after incubation in medium alone (background) or in the presence of a mitogen. Each point represents the mean counts per minute (cpm) for quadruplicate cultures. Time on the abscissa refers to the time after injection of APS into the mice that spleen cells were collected and cultured.

types displayed hallmarks of stimulated megakaryocytopoiesis after an injection of APS that have been found in other strains^{4,5,20} and other species^{1-3,21-26}: macromegakaryocytosis and rebound thrombocytosis. Numbers of megakaryocytes increased in nu/+ mice two days after injection of APS, but

Fig 7. Serial observations of tritiated thymidine incorporation into 5×10^5 spleen cells from nu/nu and nu/+ mice after injection of NGpS. Assays were performed after incubation in medium alone (background) or in the presence of a mitogen. Each point represents the mean counts per minute (cpm) for quadruplicate cultures. they did not significantly increase in nu/nu mice. Because of variability in the increase in megakaryocyte numbers after a single injection of APS, it is unlikely that this signifies an important difference between nu/nu and nu/+ mice.

Increases in number and size of megakaryocytes, thought to be due to thrombopoietin *in vivo*,²⁷ resemble the effects of megakaryocyte potentiator activity on megakaryocyte colonies *in vitro*.²⁸ It has recently been reported²⁹ that mitogen-activated murine T lymphocytes produce potentiator activity, thus possibly also explaining augmentation of growth of human megakaryocyte colonies by activated T lymphocytes.³⁰ It was suggested that T cells may play an important role in amplifying platelet production in response to inflammation or infection.²⁹ However, the present results demonstrated that a full complement of T cells was not necessary either to maintain normal platelet production or to augment platelet production in response to acute immunothrombocytopenia. Furthermore, the increase of splenic Meg-CFC in nu/nu mice, following administration of NGpS (which did not alter platelet levels), demonstrated that these T cell-deficient mice were capable of responding to an immunological challenge, as has been previously described in C57B1 mice.⁴

As determined by mitogen (PHA and Con A)-induced DNA synthesis, the untreated nu/nu mice used in these experiments had no demonstrable T cells in their spleens. However, others have reported that nu/nu mice are not completely lacking in T cells, but have low numbers of cells that react with antibodies to T cell antigens (reviewed in reference 31). Such cells do not prevent nude mice from accepting grafts of foreign tissue and do not provide the immunological support necessary for a normal life span. Likewise, spleen cells from nu/nu mice, of approximately the same age as those utilized in our experiments, do not appear capable of producing interleukin 2.³² However, it is possible that the small numbers of T cells that are demonstrable with antibodies represent a selected population of T cells that might have hematopoietic regulatory capability. If so, their identification and further study would be of great interest. Macrophages from nu/nu mice have been found to have greater bactericidal activity than those from normal mice.³³ Therefore, it is noteworthy that macrophages have been identified as a potent source of potentiator activity that induces megakaryocyte differentiation *in vitro*.²⁸ Thus, macrophages might have accounted for the normal stimulation of thrombocytopoiesis in nu/nu mice. However, it is also equally possible that neither T cells nor macrophages were involved and that regulation of platelet production is independent of these cell types.

It also has been reported that athymic, but not euthymic, mice have splenic cells capable of suppressing the response of spleen cells to the B cell mitogen LPS.³⁴ If such suppressor cells were activated by the platelet antigen-antibody reaction, the delayed tendency for spleen cell responsiveness to LPS to decline in nu/nu mice after APS but not after NGpS might be explained.

Levels of ³HTdR incorporation that were higher than background were detected on four occasions when nu/nu spleen cells were incubated with the T cell mitogens PHA or

Con A. In all cases the level of incorporation (cpm/ 5×10^5 cells) was considerably less than that found in control spleen cells. However, T cell recruitment, as demonstrated by mitogen responsiveness, did not appear to account for the stimulation of thrombocytopoiesis that was observed in response to immunothrombocytopenia, because only six days after APS injection did nu/nu mice show a weak mitogenic response. By that time, platelet counts were at rebound thrombocytotic levels, and megakaryocyte number and size had returned to normal; that is, stimulation of megakaryocytopoiesis had already run its course.

Similarly, correlations between changes in numbers of colony-forming cells and the state of thrombocytopoiesis in these mice are not obvious. The nu/nu mice showed delayed increases in splenic Meg-CFC after APS or NGpS and in splenic GM-CFC after APS, but thrombocytopenia and stimulation of thrombocytopoiesis occurred only after APS. However, platelet counts on the sixth day after APS were significantly higher in nu/nu than in nu/+ mice. Therefore, it could be proposed that splenic hematopoiesis, as shown by elevated levels of Meg-CFC and GM-CFC in nu/nu but not nu/+ spleens, may have accounted for the difference in platelet levels. Neither Meg-CFC nor GM-CFC increased in the nu/nu bone marrow. The changes in splenic and bone marrow CFC in nu/nu mice resembled those previously described in C57B1 mice,^{4,5} but increases in the spleen were of lesser magnitude and duration. In contrast, nu/+ controls unexpectedly showed no delayed increase in Meg-CFC or GM-CFC in the spleen, but numbers of Meg-CFC were increased in the marrow four hours after APS or NGpS, and numbers of marrow GM-CFC were increased four hours after APS. Since there were no clear-cut differences in thrombocytopoiesis in the two genotypes during the first five days after administration of APS, the influence of these early increases in Meg-CFC and GM-CFC in the marrow on subsequent megakaryocytopoiesis is not clear. These data

suggest that strain differences in CFC responses may exist, and they show that similar thrombocytopoietic alterations can accompany different Meg-CFC and GM-CFC responses to perturbation.

Changes in numbers of CFC could not be attributed directly to thrombocytopenia or to an indirect effect of thrombocytopenia on the marrow, because they also occurred in mice injected with NGpS, which did not produce thrombocytopenia. Similar responses to normal heterologous serum also have been observed in C57B1 mice, and it was postulated that stimulation of the reticuloendothelial system played a role in the response.⁴ In addition, increases in GM-CFC occurred in the marrow of nu/+ mice and the spleens of nu/nu mice only after APS, whereas increases in Meg-CFC followed administration of either APS or NGpS. Others^{5,26} have reported that the proportion of Meg-CFC in DNA synthesis increases in response to thrombocytopenia even if numbers of Meg-CFC do not increase.²⁶ Thus, cell cycle status, which was not measured in our experiments, may be a more sensitive indicator of the involvement of Meg-CFC in thrombocytopoiesis than is their number.

The observations that hematocrits and bone marrow cellularity were lower than normal in nu/nu mice confirms reports of others.^{14,35} Marrow hypocellularity has been reported to be due mainly to low numbers of erythrocytic and lymphocytic cells.¹⁴

In summary, our data indicated that T cell-deficient nu/nu mice regulated thrombocytopoiesis normally both in the unperturbed steady state and in response to acute immunothrombocytopenia. This suggests either that T cells were not required for the regulation of platelet production *in vivo* or that T cell thrombocytopoietic regulatory function resided in the small population of T cells that exists in nu/nu mice. Delayed and nonspecific responses of Meg-CFC suggested that quantitative changes in these cells were not essential for the response to acute immunothrombocytopenia.

Studies on B Lymphoid Tumors Treated With Monoclonal Anti-idiotype Antibodies: Correlation With Clinical Responses

By James N. Lowder, Timothy C. Meeker, Michael Campbell, Carlos F. Garcia, Julie Gralow, Richard A. Miller, Roger Warnke, and Ronald Levy

Monoclonal anti-idiotype antibodies can be made which are exquisitely specific for B lymphocytic malignancies. We have conducted a clinical trial in which some patients' tumors regressed after infusion of such antibodies. Here, we evaluated characteristics of the antibodies, the tumors, and the patients to determine which features best correlated with the clinical response. Neither the isotype of the murine antibodies, nor their avidity were predictive of clinical outcome. The specific epitope to which the antibodies bound was characterized by immunochemical techniques. Reactivity with a heavy-light chain combinatorial determinant correlated somewhat with clinical effect. Variations in the characteristics of the individual tumors such as antigen sites per cell and ability to modulate the

surface immunoglobulin were not predictive of response. In one patient with prolymphocytic leukemia the anti-idiotype antibody had a direct antiproliferative effect on tumor cells in vitro. This patient's tumor response was explainable by such a direct mechanism. In the other patients, who had lymphomas, therapeutic outcome correlated with the number of host nontumor cells infiltrating the tumor. The vast majority of these nontumor cells were mature T lymphocytes of the Leu 4, Leu 3 (T3, T4) phenotype. Thus, a preexistent host-tumor interaction seems to be important in the in vivo effect of anti-idiotype antibodies in B cell tumors.

© 1987 by Grune & Stratton, Inc.

THERAPY WITH MURINE monoclonal antibodies (MoAbs) directed against human tumor cell surface antigens has been tested in several clinical trials.¹⁻¹² Antibodies specific for the idiotype of the surface immunoglobulin (Ig) of B cell malignancies have been among the most successful in inducing regressions of tumor.^{1,3} In our clinical trial, six of ten evaluable patients experienced clinically significant responses of disease during MoAb therapy. One patient's disease regressed completely. Of the five others who experienced a partial response, four had virtually all the tumor which reacted with the antibody eradicated. In those four cases, the original tumor population was replaced by mutant tumor cells which were unreactive with the antibody.^{13,14} However, four other patients treated with anti-idiotype antibodies had no tumor response. It is important to determine which variables pertaining to the antibodies, tumors, or patients may have influenced the clinical outcome. We previously described a correlation between the numbers of normal T cells infiltrating the tumor with response to anti-idiotype antibody therapy.¹⁵ Other variables may also be important. A unique antibody was developed for each patient. Thus, the antibodies potentially differed from each other in isotype, in avidity of binding, and in epitope specificity.

In addition to the properties of the antibodies, differences in the tumors are potentially important. Normal B lymphocytes are responsive to many regulatory substances which promote or inhibit proliferation and/or differentiation.¹⁶⁻²³ Anti-Ig or specific antigen, which, like anti-idiotype antibodies, bind to the surface immunoglobulin, can stimulate or inhibit the proliferation of normal B cells, even in the absence of other mitogenic factors.^{16-18,23,24} Jerne proposed that autologous anti-idiotype antibodies exert a major inhibitory force on B cell clones in the immune response.²⁵ In addition, the maturational state of B cells greatly influences their dependence on growth factors and their receptiveness to immune control, including that mediated by anti-Ig antibodies.^{16,17} B cell tumors appear to represent various stages of normal differentiation, reflected by their morphologic appearance,

ability to secrete immunoglobulin, and tissue localization. By analogy, the differentiation state of a tumor may alter its response to anti-idiotype antibody.

Patients with B cell lymphoma can be immune deficient as a consequence of their disease and/or treatment.^{3,26,27} Anergy, frequent infections, hypogammaglobulinemia, and cytopenias are common problems in patients with B cell malignancies, but vary in severity from patient to patient. These patients might thus have effector systems for antibody-mediated tumor responses. The natural history of low grade B cell lymphoma is characterized by long periods of quiescent disease and occasionally spontaneous regressions.²⁸ Some host antitumor response may be operative in these patients and the anti-idiotype antibody might augment that interaction.

Thus, analysis of the factors important in determining the outcome of anti-idiotype treatment is complicated by the large number of variables. Each patient, his tumor, and his antibody are unique. In this study, we attempted to correlate a variety of in vitro studies of the antibody, tumor, and patient with the clinical response.

MATERIALS AND METHODS

Patients

Patients in this study and their treatment with anti-idiotypic antibody were described in detail in a prior publication.³ Briefly, all patients had B lymphoid malignancies, eight with nodular lymphoma and one each with large cell lymphoma, prolymphocytic leukemia, and diffuse small cleaved cell lymphoma with foci of large cell lymphoma. Monoclonal anti-idiotypic antibodies were made for each patient's tumor as previously described.²⁹ Tumor samples obtained from the peripheral blood, bone marrow, lymph nodes, skin masses, or spleen of each patient had been frozen in liquid nitrogen and were available for this study either as viable cell suspensions or as frozen tissue fragments.

Immunophenotyping and Enumeration of Subsets

Tumor samples taken prior to therapy were evaluated by routine pathologic analysis, immunoperoxidase staining of frozen sections, and immunofluorescence analysis of single cell suspensions using methods that have been previously described.³⁰⁻³³

Rescue Hybridization

In order to obtain idiotypic protein from the nonsecreting tumor cells, "rescue fusions" were performed with mouse myeloma or heteromyeloma cells as previously described.^{34,35} The resulting hybrids were screened for secretion of human heavy and light chains of the appropriate type by enzyme-linked immunosorbent assay (ELISA). The secreted proteins were purified by immunoaffinity chromatography and used in the assays described below.

Quantitation of Surface IgM

The relative amount per cell of surface immunoglobulin on the different tumors was obtained by flow cytometry using the FACS 440 fluorescence-activated cell sorter (Becton Dickinson, Mountain View, Calif) by methods previously described.³ The mean linear fluorescence intensity³⁶ was determined on single cell suspensions of tumor stained with a fluorescein isothiocyanate (FITC)-conjugated monoclonal antibody, 1D12, which is reactive with human μ heavy chain.

Binding constant determination

Equilibrium plate method. Anti-idiotypic antibody was metabolically labelled with ⁷⁵Se-selenomethionine (Amersham Co, Arlington Heights, Ill). Approximately eight million hybridoma cells were incubated for 16 hours in methionine-free RPMI 1640 (GIBCO, Grand Island, NY) containing 5% dialyzed heat-inactivated fetal calf serum. After the labelling period, cells were removed by centrifugation and the supernatant was dialyzed extensively against phosphate buffered 0.9% saline (PBS) to remove unincorporated label. The concentration of anti-idiotypic antibody in the labelled supernatant was determined by immunoassay. The percent of protein-bound radioactivity in the form of active antibody was determined by binding at equilibrium to a vast excess of idiotypic (tumor cells) or goat anti-mouse Ig (coupled to Sepharose beads). The fraction of the total radioactivity that was bindable varied from 24% to 50%.

The binding constant determination was performed in a microtiter plate (Cooke Engineering, Alexandria, VA). Wells were coated with 100 μ L of diluted idiotypic protein or an irrelevant IgM and then incubated with 150 μ L of PBS/bovine serum albumin (BSA) for one hour. After washing, 100 μ L of serially diluted labelled anti-idiotypic was added to the wells. After a six-hour incubation at room temperature, the supernatants were removed and the plates were

quickly washed four times. The dry wells were cut with a hot wire device and counted in a gamma counter. All experimental points were measured in triplicate.

The free counts in each well were determined by subtracting the bound counts from the total input counts. The ratio of bound/free was plotted v bound and a slope of their curve was determined,³⁷ and the binding constant was determined according to the following equation:

$$K = \frac{-(\text{slope})(SA)10}{4.44(\text{mol wt})} \times 1.4(\text{vol})$$

SA = cpm/ μ g
vol = 0.1 mL
mol wt = 150,000

Soluble complex method. The second method used to measure antibody avidity was a modification of the method reported by Griswold and Nelson.³⁸ This method is based upon thermodynamic principles which predict that the binding of antibody to antigen will decrease as the total reaction volume is increased, provided the number of moles of antigen and antibody are held constant. The rate of this decrease is related to antibody avidity.

The assay was performed by mixing anti-idiotypic with a 3-fold excess of idiotypic, and diluting this mixture 1:5 and 1:10 into PBS/10% fetal calf serum. After a four-hour incubation, 50 μ L aliquots of these mixtures were added, in quadruplicate, to wells of a 96-well microtiter plate coated with goat anti-mouse IgG antibody. The concentration of mouse anti-idiotypic initially mixed with idiotypic was previously determined to be nonsaturating on the anti-mouse IgG coated plate. After another four-hour incubation, plates were washed and a horseradish peroxidase (HRP)-coupled goat anti-human IgM antibody was added followed by 2,2'-azino-di-(3-ethylbenzthiazoline) sulfonic acid (ABTS) substrate to detect anti-idiotypic-idiotypic complexes bound to the plate. Avidity was calculated utilizing the BASIC program described by Griswold and Nelson.³⁸ Given the initial idiotypic concentration, the dilution factor, and the fraction idiotypic bound at two different reaction volumes the program determines an avidity value using a binary search algorithm.

Western Blots

Probing of purified proteins with radioactive antibodies was performed following the method of Burnette.³⁹ Idiotypic protein from each patient was electrophoresed in a 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) system in both reduced and unreduced states. The protein was electrophoretically transferred to nitrocellulose (0.45 μ m, Millipore, Bedford, MA) overnight. The nitrocellulose was incubated 2 to 8 hours in PBS/5% nonfat dry milk (Carnation, Los Angeles) (PBS/NFDM). First stage antibody at 5 to 10 μ g/mL in PBS/NFDM, was followed by an ¹²⁵Iodine-labelled goat anti-mouse Ig (TAGO, Burlingame, Calif) also in PBS/NFDM. The nitrocellulose was washed between steps with 0.9% saline and 0.9% saline/0.05% NP-40. Autoradiography was performed after the last wash.

Blocking of a Monoclonal Antihuman μ (clone 1D12) with Antiidiotypic Antibody

Further definition of the fine epitope specificity of the anti-idiotypic antibodies was determined by their ability to compete for binding with a murine IgG1 MoAbs specific for human μ heavy chain, to the appropriate idiotypic protein. Tumor cells stained by directly fluoresceinated 1D12 antibody in the presence or absence of anti-idiotypic antibody were analyzed by flow cytometry and their mean fluorescences were compared. Tumor cells frozen in 10% dimethyl sulfoxide (DMSO) were thawed and viable cells were isolated using Ficoll-Hypaque density gradient centrifugation.

Twenty-minute incubations of 10^6 cells with 100 μ L of 10 μ g/mL of first stage antibody diluted in PBS/BSA/0.01% sodium azide were performed at 0°C. The cells were washed twice with cold PBS/BSA/azide. The final antibody, 1D12FITC, was added to the cells which were incubated on ice, washed, and then fixed in 10% paraformaldehyde in PBS. Twenty thousand cells were counted in the flow cytometer and their mean fluorescence in linear units was determined.⁴⁴ The percent blocking was determined using the following equation:

% blocking

$$= 1 - \frac{(\text{mean F anti-id} + 1\text{D12FITC} - \text{background F})}{(\text{mean F irrelevant MoAb} + 1\text{D12FITC} - \text{background F})} \times 100$$

Modulation of Surface Idiotype Immunoglobulin

Aliquots of single cell suspensions of frozen biopsy specimens were thawed and viable mononuclear cells were separated by Ficoll-Hypaque density gradient centrifugation. In order to induce modulation, aliquots of the tumor cell suspension were incubated with MoAbs in 5% CO₂ at 37°C for varying periods of time. Cultures were started at different times to allow simultaneous staining of cells incubated for 0, 1, and 24 hours. After incubation, the cells were washed extensively with PBS/BSA and then stained for flow cytometry as described above. First stage antibodies used in the staining included an appropriate irrelevant MoAb, the appropriate anti-idiotype MoAb, and 1D12 MoAb. Binding of MoAb to the cells was detected with fluoresceinated goat anti-mouse IgG. The mean linear fluorescence was determined using a FACS IV (Becton Dickinson, Mountain View, Calif).⁴⁰ The percent modulation observed for a particular time and MoAb concentration was determined as follows:

$$\% \text{ modulation} = 1 - \frac{(\text{mean F modulated tumor}) - (\text{mean F tumor} + \text{second step})}{(\text{mean F unmodulated tumor}) - (\text{mean F tumor} + \text{second step})} \times 100$$

Tumor Cell Proliferation Assays

Two hundred thousand viable cells obtained from either a pretherapy tumor biopsy or peripheral blood mononuclear cells, if more than 90% were idiotype positive, were added to a 96-well microtiter plate in 200 μ L of complete medium supplemented with sodium pyruvate (1 mmol/L) and 2-mercaptoethanol (10^{-4} mol/L). One half of the wells also contained 1 μ g/mL phytohemagglutinin (PHA) (Wellcome, Greenville, NC) and phorbol myristate acetate 10 ng/mL (PMA) (Sigma Chemical Co, St. Louis, MO). To triplicates the appropriate anti-idiotype antibody, 1D12 (anti μ) or an isotype matched control antibody were added at a concentration of 10 μ g/mL. The plates were incubated in 5% CO₂ at 37°C for 2, 4, or 6 days and then pulsed with ³H-methylthymidine at a concentration of 1 μ Ci per well. The cells were harvested and counted as previously described.²¹

RESULTS

Murine Antibody Isotype

The isotypes of the MoAbs used to treat the eleven patients are listed in Table 1. Strict criteria were used to define the specificity of each anti-idiotype antibody, and antibodies only of the IgG class were selected. However, no selection was imposed for IgG subclasses. In most instances the first hybridoma clone obtained with the appropriate specificity and stability was chosen for the therapeutic trial. The higher frequency of IgG1 anti-idiotype MoAbs reflects their greater frequency among all the hybridomas generated. Six patients received IgG1, two IgG2a, two IgG2b, and one received three antibodies, one of each isotype. There was no correlation in this study between the IgG subclass of the antibody and the occurrence of a tumor response. The only patient to achieve complete elimination of tumor received an IgG2b antibody; the next most dramatic responder was treated with an IgG2a. However, four of six patients infused with IgG1 anti-idiotype MoAb experienced objective

responses. Two other evaluable patients treated with IgG2 antibodies had no response.

Idiotypic Protein

All tumors described in this study expressed IgM on their cell surface. Four expressed λ light chain and seven expressed κ light chain. Six patients (one λ , five κ) secreted IgM which could be detected in the serum in concentrations of 0.1 to 400 $\mu\text{g/mL}$.³ This secreted idiotypic protein was an IgM pentamer as determined by gel electrophoresis of samples isolated from the serum of two patients and from supernatant from "rescue hybrids" of the tumors of three others³⁴ (unpublished data). Although the presence of free idiotype protein in the serum could block binding of anti-idiotype to cellular idiotype, it did not preclude a favorable therapeutic result if a dose of anti-idiotype MoAb sufficient to achieve extravascular penetration was infused.

Estimation of the amount of surface IgM per tumor cell, revealed a sevenfold difference between the highest and lowest of the tumors tested (Table 1). The tumor cells from patient FS, with prolymphocytic leukemia, had nearly twice as much surface Ig as the next highest expressing tumor. Cells of the majority of patients clustered in the lower range, and there was no correlation between surface Ig expression and clinical response.

Epitope

The surface IgM of each individual tumor has a unique variable region with its own idiotypic determinants, but the majority of the molecule is made up of constant protein sequences shared by them all. The anti-idiotype MoAbs were by definition specific for determinants dependent upon the variable regions of the heavy and/or light chains of the tumor specific immunoglobulin. This epitope could be further defined by several methods. A particular MoAb, 1D12, which is specific for the human μ heavy chain and presumably reactive with a determinant in the constant region proximate to the variable region, could be significantly blocked by six of the ten anti-idiotype antibodies that were tested (Table 1). It is unclear whether the anti-idiotype antibodies that block sterically hinder the binding of 1D12 or if their binding produces changes in the tertiary structure which alter the 1D12 binding site. Different anti-idiotype antibodies against the same IgM molecule can differ in their effects on 1D12 antibody binding presumably because they bind to different sites (idiotypes) (Fig 1).

Immunoblots of reduced and unreduced idiotype protein provided additional information about the idiotypic determinant recognized by each antibody (Table 1). This technique can distinguish between antibodies which bind to an idiotope located on the isolated heavy or light chain, separated by gel electrophoresis after reduction, from those that require the intact immunoglobulin. Examples of both situations are displayed in Fig 2. In two cases, the electrophoresis procedure produced changes in the conformation of the idiotype of the unreduced molecule which prevented binding by the antiidiotype antibody.⁴¹ The sodium dodecyl sulfate used in the electrophoresis was believed to be the factor

Fig 1. Anti-idiotype antibody blocking of 1D12. Histograms show the logarithmic fluorescence intensity after staining of a cell line derived from the tumor of patient KL which expressed idiotype-positive surface IgM. The cells in each histogram were stained with 1D12 anti- μ MoAb conjugated to fluorescein isothiocyanate (1D12-FITC) as a second step. The solid line in each panel represents initial incubation of the cells with a nonbinding isotype control antibody, showing maximal staining with the 1D12-FITC. The dashed line represents cells incubated previously with unconjugated antibody, (A) 1D12, (B) 22.7 anti-idiotype, (C) 17.6 anti-idiotype, and (D) 9.15.17 anti-idiotype. Displacement of the curve to the left represents the relative ability of the first step antibody to block the binding of 1D12-FITC to its epitope.

responsible and after washing with urea and NP-40 the binding site was restored in one of these two cases.⁴² Of eight idiotype proteins evaluable by this method, five reacted only with the assembled heavy-light chain molecule and three reacted with both the isolated heavy chain and the intact antibody. None of the anti-idiotype MoAbs reacted with the free light chain.

The ability to block 1D12 and the chain reactivity on Western blot analysis did not correlate with each other and appear to evaluate different facets of idiotype fine specificity. Blocking of the 1D12 binding site did not correlate with clinical outcome. However, the data do suggest that reactivity with an HL combinatorial determinant may be important, that is, 4/5 responders *v* 1/2 nonresponders had HL reactivity.

Binding Constants

Another potentially important feature of the anti-idiotype antibodies is their affinity or avidity. Determination of affinity requires accurate measurements of the concentrations of free and antibody-bound antigen under various conditions. In this case, both antigen and antibody are large proteins and complexes cannot be easily separated from free

Fig 2. Immunoblotting of idiotype proteins with anti-idiotype antibodies. Idiotype protein was subjected to SDS-PAGE under reducing lanes 1 and 2 (R) and nonreducing lanes 3 and 4 (UR) conditions and electroblotted onto nitrocellulose membranes. Purified idiotype from patient PK (panel A) and CJ (panel B) were probed with the appropriate anti-idiotype (anti-id) or isotype matched control (C) antibodies and binding was detected with ^{125}I -goat anti-mouse Ig. Anti-idiotype for patient PK reacted with only the combined heavy and light chain and not with the isolated heavy or light chain. Anti-idiotype for patient CJ reacted with both isolated heavy chain and the intact molecule.

antigen. Two relatively independent methods were used to determine the binding constants of the anti-idiotypic MoAbs for which purified idiotype was available (Table 1). Both methods partition unbound antibody from bound antibody by fixing the immune complexes to a solid phase. In the equilibrium plate method the concentrations of bound and free anti-idiotype antibody are determined after interacting with the idiotype which was initially fixed to a plastic plate. The soluble complex method measures the amount of soluble complex formed by a fixed ratio of antibody and antigen at different total protein concentrations. These independent methods are clearly in agreement regarding the rank order of avidity of the MoAbs studied and remarkably close in their absolute values. A thousandfold difference existed between the most avid (PE) and the least avid (RD) antibodies. The highest and lowest values, however, were outside the most accurate quantitative range of both assays and the numerical values assigned to these two cases are less precise than the others. The rank order of these antibodies, however, is clear, and there was no correlation between this feature of the antibody and clinical response.

Modulation

Surface immunoglobulin, like many cell surface proteins, can move within the plane of the membrane and when cross-linked by multivalent antibody may be internalized causing the disappearance (modulation) of the surface antigen. The anti-idiotypic MoAbs caused a variable degree of modulation of cell surface idiotypic immunoglobulin both in vitro and in vivo. Fig 3 demonstrates differences in the modulability by their respective anti-idiotypic antibody of the tumors tested. The time dependence of modulation can be appreciated, as all tumors demonstrate increased modulation between one and 24 hours of incubation. Considerable variation existed among the tumors as to the maximal modulation which could be induced. CP exhibited no modulation at the $1\text{ }\mu\text{g/mL}$ concentration of anti-idiotypic MoAb and significantly less than the others at the higher concentration. Others were able to modulate 50% to 90% over 24 hours. Tumor cells of patient CG underwrote modulation in vivo as demonstrated in a lymph node specimen removed during treatment with anti-idiotypic MoAb (data

Fig 3. Modulation of surface immunoglobulin by anti-idiotype antibody. The tumor cells evaluated in Fig 3 were incubated for varying times with 1 or $10\text{ }\mu\text{g/mL}$ of anti-idiotypic antibody. After staining with FITC-labeled goat anti-mouse Ig, the mean fluorescence of the cells was determined and related to that for cells incubated with a nonbinding control. Complete disappearance of surface immunoglobulin is equivalent to 100% modulation. The analysis was not performed on patients PK, BJ, CG, KL, and PE.

Fig 4. Modulation of surface immunoglobulin by 1D12 antibody. The patient's tumor cells were incubated for varying times with 1D12 (anti- μ chain MoAb) at a concentration of 10 μ g/mL. The percent modulation was determined as described in Fig 3.

not shown). Modulation appeared to be a function of both the biologic behavior of the tumor cell and the MoAb used. Modulation induced by the anti- μ MoAb 1D12 (Fig 4) was similar to that induced by the anti-idiotypic MoAb, however, the rate at which it occurred and the absolute degree of surface antigen decrement varied. Avidity, epitopic specificity, and clinical response did not correlate with in vitro modulation.

Effects of MoAb on In Vitro Proliferation of Tumor

In order to investigate whether the anti-idiotypic MoAbs had a direct effect upon their respective target tumor cells, we cultured the cells in vitro with the anti-idiotypic or with the anti- μ 1D12 antibodies in the presence or absence of mitogens PHA and PMA for up to seven days. The results

are displayed in Table 2. The addition of the mitogens PMA and PHA increased the baseline proliferation of the cells by a factor of three to ten (Table 2A), but the effects of the antibodies were the same whether or not the mitogens were present (Table 2B). The cells incubated without antibody maintained a stable proliferative state over the seven-day period. Three of the tumors were unaffected by the addition of either the anti-idiotypic or the anti- μ antibody. Two other tumors were mildly affected (TG was suppressed; BL was stimulated) by both their respective anti-idiotypic antibody and by anti- μ . Neither of these patients experienced any change in their tumors upon treatment with their anti-idiotypic antibodies. By contrast, tumor cells from patient FS were markedly suppressed by both anti-idiotypic and anti- μ MoAb. This patient, with prolymphocytic leukemia, had a dramatic and sudden response to anti-idiotypic antibody therapy, in contrast to the rather gradual responses observed in other responding patients.³ The rapid tempo of the clinical response in patient FS and the unusual susceptibility of his tumor cells to a direct antiproliferative effect by anti-Ig antibodies in vitro suggest the mechanism for his response was different from that for the other patients.

Host Factors

The various tissues obtained from the patients were analyzed by immunofluorescence and flow cytometry of cells in suspension and by immunoperoxidase staining of frozen tissue sections. All specimens contained numerous infiltrating normal cells. As previously reported,¹⁵ the normal host cells infiltrating the tumor were composed primarily of T lymphocytes. These T cells were predominantly of the Leu 3, Leu 4 (T4, T3) positive (helper) phenotype (Table 3). Smaller numbers of Leu 2, Leu 4 (T8, T3) positive (cytotoxic, suppressor) T cells were also present, as were a small,

variable number of Leu 7 positive (NK/K) cells. Leu 7 positive cells were large and localized to follicles in patients with follicular histology. In patients with follicular diseases the host infiltrate cells were localized predominantly in the interfollicular areas.

Interestingly, we observed that ratios of malignant B cells to nontumor T cells existed which were characteristic for each patient. For instance, in one patient, pretherapy specimens were obtained from three different tissue sites (lymph node, skin, and bone marrow) at two separate time points. All three biopsies were found to have maintained a similar ratio of tumor cells to host infiltrate (Fig 5).

There was a correlation between the number of nontumor T cells present in biopsy specimens prior to anti-idiotypic therapy and the response to that therapy (Fig 6). This correlation was especially striking in view of the failure of the many other parameters of the therapeutic MoAb, the tumor cell, and the host mentioned above to predict response to anti-idiotypic therapy. Of the two patients with tumors containing 56% to 80% Leu 4 positive cells in the biopsy, the disease in one completely remitted with anti-idiotypic MoAb and that in the other showed an impressive response. The difference in the proportion of T cells in these two patients compared to the other patients was statistically significant ($P < .001$). The patients with lesser responses had between 23% and 34% Leu 4+ cells in their pre-MoAb therapy tissue biopsies. The patients who had no tumor response all had less than 16% T cells in their specimens. This evaluation excludes patient FS, whose disease was a leukemia rather than a lymphoma and whose tumor response appeared to be mediated by a direct antiproliferative effect.

DISCUSSION

A series of patients with B cell malignancy has been treated with MoAbs directed against an idiotypic determinant of the immunoglobulin molecule present on the

surface of their tumor cells. A spectrum of clinical outcomes has been observed, ranging from complete and durable remission to no effect.^{1,3} Some of the factors that influence the therapeutic outcome have been previously identified and include the presence in the serum of idiotype protein, the occurrence of an immune response against the foreign MoAb, and the existence within the tumor population of cells with mutations of the idiotype.^{3,13,14} In view of these obstacles, it is remarkable that clinically significant tumor regressions have occurred in over half of the patients who have been studied. In fact, the emergence of tumor cells with idiotype mutations during therapy with an anti-idiotypic antibody implies that the antibody exerted a strong selective force against the idiotype-positive tumor cell population in these cases.

In the current report we have presented a series of studies to elucidate the mechanism of the antitumor effect of the anti-idiotypic antibodies. Since each patient, tumor and antibody were unique and only limited amounts of pathologic material were available from some of the patients, exhaustive studies were difficult to perform. Nevertheless, we attempted to examine the relative roles of the antibody—its class, affinity, and epitope; the tumor—its responsiveness to direct effects of anti-idiotypic antibody and the surface density and modulability of its Ig molecule; and the host—the nature and composition of the cellular infiltrate within the tumor tissue.

The known mechanisms of in vitro antibody mediated cytotoxicity include complement fixation and antibody-dependent cell-mediated cytotoxicity (ADCC). Both of these functions are highly dependent on antibody class as well as the availability of the effector molecules and/or cells. Kipps et al have recently documented the superiority of murine IgG2a over IgG2b and IgG1 antibodies in performing ADCC in vitro with human effector cells,⁴³ and numerous studies in animal models have likewise suggested a superiority of IgG2a antibodies for in vivo antitumor effects.⁴⁴⁻⁴⁶

Fig 5. Relative numbers of infiltrating host T Lymphocytes and malignant B cells are demonstrated by immunoperoxidase staining of frozen sections of pretherapy tumor specimens from patient PE. Simultaneous biopsy of lymph node (A,B) and subcutaneous mass (C,D) were performed in April 1982. A bone marrow biopsy (E,F) was performed in August 1984 immediately prior to treatment with anti-idiotype antibody. Frozen sections of each biopsy specimen were incubated with anti-Leu 4, which binds to mature T lymphocytes, (A,C,E), or an antibody specific for a B lymphoid cell surface marker (B-anti- μ , D-anti-B1, F-anti- μ). Cells binding antibody were detected with an immunoperoxidase method and the specimen was counterstained with methylene blue. The large excess of host T lymphocytes to tumor cells is maintained over time and in various tissues involved with tumor.

There was no clear relationship in our clinical trial between antibody class and outcome. Although the most dramatic responses occurred with antibodies of the IgG2 class (one IgG2a and one IgG2b), responses occurred with antibodies of the IgG1 class as well. In addition, we have not observed a

correlation between changes in serum complement levels and clinical outcome. The observations tend to argue against an important role for a direct cytotoxic effect of anti-idiotype antibodies, although they do not rule out such a mechanism.

Whatever the mechanism of antibody effect, it seemed

Fig 5. (Cont'd).

likely that the avidity of interaction between antibody and idiotype target should be important. Two different methods were used in this study to estimate antibody avidity. The results were in close agreement, and certainly there was concordance in the rank order of the different antibody-idiotype combinations. Over the range of avidity covered by these particular antibodies no correlation existed with clinical outcome. Apparently the methods that were used to select MoAbs resulted in antibodies of sufficiently high avidity to produce *in vivo* effects.

Although idiotypic determinants are located somewhere within the variable regions of the immunoglobulin heavy and light chains, different anti-idiotypic antibodies can recognize different parts of the variable region structure. For instance, in cases of myeloma proteins which bind known antigens, some anti-idiotypic antibodies inhibit antigen binding and some do not.⁴⁷⁻⁴⁹ If anti-idiotypic antibodies exert a direct regulatory effect on the B cell which bears the relevant target molecule on its surface, the exact portion of the V region to which they bind may be of critical importance in signal transduction. Since in B cell lymphomas no antigen is known to bind to the cell surface idiotype, we used two alternative approaches to investigate the idiotypic determinants. A MoAb reactive with the μ heavy chain was blocked from binding to its respective epitope by certain anti-idiotypic antibodies. Evidently, this anti- μ antibody reacted with a site in the C μ region near the V-C junction. We could then infer that some of our anti-idiotypic antibodies reacted with a site nearby. Some idiotypic determinants are created by a combination of heavy and light chain structures, and others are dependent only upon one of the chains. We tested the antibodies which were used in the therapeutic trials for their ability to react with isolated chains and found that several of

them reacted with determinants on the heavy chains. Steric hindrance of an anti- μ chain antibody showed no correlation with outcome whereas reactivity with an HL combinatorial determinant did show some correlation with clinical effectiveness *in vivo*.

Direct effects of anti-idiotypic or anti-Ig antibodies on normal and neoplastic B cells have been demonstrated in a number of *in vitro* systems.^{16-18,23,24,50,51} These effects have included stimulation of proliferation, inhibition of proliferation, and induction of receptors for BCGF and IL2. The differences seem to depend upon the *in vitro* system, the particular anti-Ig reagent and the state of differentiation of

Fig 6. Impact of T cells on response to anti-idiotypic therapy. The percent of Leu 4 or Leu 1 positive cells, as determined by flow cytometry in the pretherapy biopsy of patients is plotted on the vertical axis and the percent response measured by lymphangiogram or computerized axial tomography is plotted on the horizontal axis. The percent of T cells is the average measured in all 15 pretherapy biopsies of the nine patients eligible for this analysis. The two patients with the best responses were biopsied two and three times prior to anti-idiotypic therapy.

the B cell target. The antiproliferative effect of anti-Ig on normal B cells can be prevented by prior treatment with mitogens.¹⁷ It was thus important to investigate the direct effects of the anti-idiotypic antibodies which were used for therapy on their respective tumor target cells. We found that the antibody used in one patient (FS) had a profound inhibitory effect on in vitro tumor cell proliferation. The antibody used in patient BL had a slight stimulatory effect, and that used in patient TG had a mild inhibitory effect on tumor cell proliferation. Those used on the other three patients tested had no measurable effect in vitro. The effects of antibody on the cells were unchanged by concomitant mitogen stimulation. The anti-idiotypic antibodies used for patients BL and TG had no in vivo effect on their tumors, either positive or negative. The kinetics of the tumor response in patient FS were consistent with a direct antiproliferative effect, since there was an acute reduction of tumor cells in the blood and bone marrow. Patient FS was different from the other patients in our series in that he had prolymphocytic leukemia, whereas the others had lymphomas. The FS tumor cells were larger and expressed markedly more surface Ig than the others. Gordon et al found EBV-transformed lymphoblastoid B cells to be inhibited by anti-Ig antibodies.¹⁸ Prolymphocytic leukemia cells might be "fixed" in a normal differentiation state susceptible to regulation by anti-idiotypic antibody.

Modulation, or "capping," of the surface antigen target by MoAb had important implications in systems in which ADCC or antiproliferative effects of antibodies were studied.^{16,23,52} Univalent (nonmodulating) antibodies have been shown to be more cytolytic both in vivo and in vitro than their bivalent counterparts which can cross-link surface antigen and produce modulation.⁵² Capping of surface Ig is required for signal transduction in the antiproliferative and toleragenic effects produced by anti-Ig antibody on neonatal murine B cells.¹⁶ Differences in the capacity for modulation were observed among the patients' tumor cells in this study which might have influenced response to therapy. However, Schroff et al demonstrated the enhancement of modulation by Fc receptor-bearing monocytes.⁵³ The in vitro modulation of the individual tumors observed in this study may have been influenced by the presence of variable numbers of macrophages/monocytes in each suspension. Similarly, the availability of Fc receptor-bearing cells during in vivo therapy might change the tumors' ability to modulate in the presence of anti-idiotypic antibody. Within these limitations, no correlation existed between in vitro modulability and clinical outcome.

In some MoAb clinical trials, the suggestion has been made that an immune response by the patients against the murine immunoglobulin was beneficial.⁵⁴ Theories have been advanced about second and third order immune responses involving idiotypic—anti-idiotypic networks, ultimately leading to an immune attack by the host against the tumor.⁵⁴ In our trial, an immune response against the murine immunoglobulin was documented in several of the patients, and in each case a portion of the response was indeed directed against the idiotypic determinant of the mouse monoclonal antibody.³ However, no support can be found in our data for

a role of the anti-mouse immunoglobulin immune response in the antitumor effect. The two most dramatic tumor regressions occurred in patients who did not make an immune response. Furthermore, in those patients who did make an immune response, no additional tumor regression was ever noted after that point in time.

Although an immune response by the host against the mouse MoAb seems unlikely to be therapeutic, an immune response against the tumor is a possible mechanism. However, this immune response seems to exist in the host prior to the introduction of the MoAb.^{14,15,55-57} In our study, there was a good correlation between clinical outcome and the number of T cells present in the pretherapy tumor tissue. In the two best responding cases the T cells actually outnumbered the tumor cells. Analysis of the cellular infiltrate showed the majority of the T cells to be of the helper/inducer (Leu 3, OKT4) phenotype in each case. Also present in this cell population were Leu 7 positive (putative NK) cells. One view would then be that the MoAb amplified or augmented an ongoing cell-mediated cytotoxic response by the host against the tumor, tipping the balance back in favor of the host. The fact that the T cells were of the Leu 3 phenotype is not inconsistent with this hypothesis, since Leu 3 positive, T killer cells that are restricted in their target cell recognition by the class II MHC structures are well described.⁵⁸ An alternative view is that the interaction between host T cells and tumor cells is a positive or trophic one. Activated T cells are a rich source of growth stimulatory factors for B cells. The fact that T cells were found associated with the tumor in relatively fixed proportions in various sites throughout the body is equally consistent with a positive as well as a negative interaction. In this view, the MoAb would be interrupting or somehow interfering with the trophic effect of the T cells on the growth of the tumor. Whether either of these mechanisms of anti-idiotypic antibody effect are operative can only be the subject of speculation at the present time. Clearly, more observations must be made as more patients are treated. Also, it will be extremely important to isolate the T cells from the tumor specimens, to measure their effects on the tumor cells, and to determine whether anti-idiotypic antibodies alter these effects.

ACKNOWLEDGMENT

The authors wish to thank Emily Chatfield and Susan Merman for their excellent secretarial support and patience in the preparation of this manuscript.

Polymorphic Glycoprotein-1 on Mouse Platelets: Possible Role of Pgp-1 and LFA-1 in Antibody-Dependent Platelet Cytotoxicity Involving Complement

By Peter J. McCaffery, An Seng Tan, and Michael V. Berridge

The presence of the Pgp-1 glycoprotein on mouse platelets is demonstrated by antibody-binding techniques, by immunoprecipitation, and by transblotting using the monoclonal antibody (MoAb) C71/26 against Pgp-1. C71/26 immunoprecipitates as a broad band of mol wt 87,000 to 100,000 as determined by radioiodination of the platelet cell surface and by the ³H-sodium borohydride labeling technique. Immunoblotting showed Pgp-1 expression on platelets to be quantitatively similar to its presence on macrophages and resolved platelet Pgp-1 into two bands of mol wt 87,000 and 97,000 whereas Pgp-1 on parasite-elicited peritoneal macrophages showed 82,000 and 87,000 mol wt species. Platelets and monocyte/macrophage cells from either peripheral blood or from the peritoneal cavity showed homogeneous binding of Pgp-1 antibody to greater than 97% of cells by flow cytometry. In contrast, lympho-

cytes from peripheral blood or from the spleen showed a heterogeneous binding pattern with 20% to 30% of cells being negative, and the majority weakly positive. In functional studies, MoAbs against CR1 and CR3 substantially inhibited platelet immune adherence, whereas C71/26 showed only marginal inhibition. In contrast, C71/26 and other MoAbs against Pgp-1 inhibited platelet-dependent cytotoxicity of antibody-coated sheep erythrocytes in the presence of C5-deficient mouse plasma whereas M1/70 against CR3 showed no effect. In this assay, MoAbs against the α - and β -subunits of leukocyte functional molecule LFA-1 also inhibited platelet cytotoxicity. These results show that the platelet cell surface moieties Pgp-1 and LFA-1 are involved in or closely associated with antibody-dependent cellular cytotoxicity by platelets.

Platelets are the second most abundant cell type in circulating blood where their primary function is hemostasis. Another well-established function for platelets is immune adherence to microorganisms through complement receptors.¹ This function appears to be restricted to certain species including rodents,^{1,2} but may be analogous to other hemostatic mechanisms involving platelet adhesion. For example, platelets bind to exposed collagen fibers following damage to blood vessel walls resulting in morphologic changes, release of α -granules and dense bodies, and platelet aggregation.³ More recently, platelets have been demonstrated to be directly involved in antibody-dependent cell-mediated cytotoxicity involving complement.⁴ Thus, mouse platelets are cytotoxic toward antibody-coated sheep erythrocytes in the presence of C5-deficient mouse serum. Furthermore, platelets from parasite-infected rats and from human subjects were able to efficiently kill *Schistosoma mansoni* larvae,^{5,6} a process involving parasite-specific IgE. Together these findings suggest that platelets may be primary mediators of immunologic destruction of systematically infecting microorganisms in both rodents and man. Furthermore, an immunologic role for platelets in cell turnover and perhaps even in tumor cell metastasis is possible.

A search for platelet cell surface molecules which may be involved in cytotoxic mechanisms revealed the presence of the leukocyte functional molecule LFA-1 on mouse platelets.⁷ In addition, the presence of complement receptor type 3 (CR3) was also demonstrated by the binding of M1/70 monoclonal antibody (MoAb) and by inhibition of immune adherence. In this study we show that C71/26 MoAb against Pgp-1, a cell surface glycoprotein present on bone marrow cells and cells of the granulocyte-macrophage lineage,⁸ also binds to mouse platelets and present evidence that this molecule may play a role in antibody-dependent platelet cytotoxicity involving complement.

MATERIALS AND METHODS

Animals and cell preparation. DBA/2, CBA/T6T6, C57B1/6, and (CBAXC57B1/6)F₁ mice were bred at Wellington Clinical School of Medicine. Platelets were prepared from whole cardiac

blood of CBA or F₁ mice, using heparin (25 U/mL) or trisodium citrate as an anticoagulant. Blood was centrifuged at 200 × g for ten minutes and platelet-rich plasma (PRP) aspirated with gentle stirring to increase the yield of platelets. Platelets were recovered by centrifuging PRP at 1,000 × g for five minutes and were washed in citrate-phosphate buffer pH 6.0 prior to use in fluorescent and solid phase assays and in immunoprecipitation. Platelet-poor plasma (PPP or plasma) was obtained either from whole blood centrifuged at 1,000 × g for ten minutes or as the supernatant from the purification of platelets from PRP. For cytotoxicity experiments platelets were resuspended in plasma from DBA mice.

Spleen, thymus, testis, bone marrow, and peripheral blood mononuclear cells isolated from the interface of Isopaque-Ficoll ($\rho = 1.09$) were prepared as washed single cell suspensions in phosphate buffered saline (PBS). Macrophages were prepared from peritoneal cells of CBA or F₁ mice chronically infected with 20 *Mesocostoides corti* larvae by repeated 1 × g sedimentation until the cell preparation contained greater than 90% macrophages. Liver, kidney, brain, and skeletal muscle were prepared by expressing tissue through a sieve and washing extensively with PBS.

MoAbs and antisera. C71/26.3.6 against Pgp-1, 121/7.7 against LFA-1 α , C71/16.2 against LFA-1 β , and 141/14.1 against T200 were obtained from Dr I. Trowbridge (Salk Institute, La Jolla, Calif); M17/5.1.9 and M17/4.4 against LFA-1 α and M1/70 against Mac-1 (CR3) were obtained from Dr T. Springer (Dana-Farber Cancer Institute, Boston); Dako-C3bR against human CR1 was obtained from Dakopatts, Copenhagen, Denmark; 2.4G2 against FcR2 from Dr J. Unkeless (Rockefeller University, New

York); EDU-3 against platelet IIb/IIIa was from Dr R. Vilella (Hospital Clinico y Provincial, Barcelona, Spain); and 1G3 was derived in this laboratory by fusion of Sp2/0 plasmacytoma cells with spleen cells from a rat inoculated with mouse platelets. All MoAbs were rat IgG except C71/26.3.6, which was rat IgM, and Dako C3bR and EDU-3, which were mouse IgG. The MoAbs used, the proteins recognized, and source references are listed in Table 1.⁸⁻¹⁴

Antithymocyte serum (ATS) and antimacrophage serum (AMS) were prepared in New Zealand white rabbits as described previously⁷ and absorbed with an equal volume of erythrocytes.

Solid phase ELISA assay. Platelet suspensions (0.1 mL, 10^7 per mL) were distributed in flat-bottomed microtiter wells (Nunc, Roskilde, Denmark) and centrifuged at $1,000 \times g$ for five minutes. Glutaraldehyde (50 μ L, 0.25% in PBS) was added to each well without having removed the supernatant, and the plates centrifuged briefly at $150 \times g$ for five minutes. Fixation was continued at 20 °C for 10 to 15 minutes. The fixative was then removed, and the cells were washed with PBS, then with PBS containing 0.05% Tween-20 (Sigma Chemical Co, St Louis) and stored frozen in this buffer. Duplicate wells were treated with the antibody to be tested (25 μ L) followed by peroxidase-conjugated IgG sheep anti-rat IgG (Amersham, Sydney) diluted to 1:800. Peroxidase substrate (0.1% o-phenylenediamine, 0.012% H_2O_2 in 0.025 mol/L citrate-phosphate buffer, pH 4.7) was added, and the reaction terminated after ten minutes by adding an equal volume of 4N H_2SO_4 . Microtiter plates were read in an automated microplate reader (Dynatech, Singapore) at 490 nm using a reference wavelength of 410 nm.

Cell surface labeling and immunoprecipitation. Purified platelets (2 to 3×10^9) in PBS were labeled either with ^{125}I -sodium iodide (Amersham, Sydney) by the glucose oxidase modification¹⁵ of the lactoperoxidase technique¹⁶ or with ^3H by mild oxidation of sialic acid residues followed by reduction with ^3H -sodium borohydride.¹⁷ The radiolabeled cells were solubilized with 1% NP-40 in 50 mmol/L Tris-HCl buffer pH 7.2 containing 10 mmol/L phenylmethylsulfonyl fluoride and 0.3 U/mL aprotinin (Sigma). Following two preabsorptions with 0.2 vol of 10% v/v *Staphylococcus aureus* Cowan strain 1 (SaCl), the cell lysates were treated with either antiserum or MoAb followed by rabbit anti-rat IgG (Miles-Yeda, Rehovot, Israel) second antibody. The resulting immune complexes were immunoprecipitated with SaCl, washed, and boiled for six minutes in SDS sample buffer (0.1 mol/L Tris-HCl, 2% SDS)

Table 1. Antibodies Used in This Study

Antibody	Specificity*	Mol Wt of Reduced Protein	Source Reference
C71/26	Pgp-1	87,000–100,000	8
I42/5	Pgp-1	87,000–100,000	8
IM7	Pgp-1	87,000–100,000	8
I21/7	LFA-1 α	170,000	9
M17/5	LFA-1 α	170,000	10
M17/4	LFA-1 α	170,000	10
C71/16	LFA-1 β	95,000	9
M1/70	CR3(Mac-1)	160,000	11
Dako-C3bR	CR1	210,000	12
I41/14	T200	200,000	Personal Communication
EDU-3	IIb/IIIa	100,000–112,000	13
2.4G2	FcRII	47,000–60,000	14

* 1 Pgp-1, polymorphic glycoprotein-1; LFA-1, leukocyte function antigen-1; α , alpha subunit; β , beta subunit; CR3, complement receptor type 3; CR1, complement receptor type 1; T200, leukocyte common molecule; IIb/IIIa, platelet glycoprotein expressing fibrinogen receptor; FcRII, Fc receptor for IgG type II.

containing 5% mercaptoethanol. SaCl was removed by centrifugation and the supernatants electrophoresed on 6% to 12.5% gradient SDS-polyacrylamide gels after the method of Laemmli.¹⁸ Autoradiography was performed using Kodak XPR-1 X-ray film (Eastman Kodak, Rochester, NY) and calcium tungstate intensifying screens.¹⁹ For immunoprecipitation with ^3H -labeled material, the polyacrylamide gels were treated with 20% 2,5-diphenyloxazole in acetic acid²⁰ and were exposed against preflashed films.²¹

Immunoblotting. Cells or washed tissue (30 μ L packed volume) that had been expressed through a fine sieve were solubilized in 1 mL NP-40 solubilization buffer (see above) and 60 μ L samples electrophoresed on 5% to 15% gradient SDS-polyacrylamide gels as described above. The gels were transblotted onto nitrocellulose sheets (Schleicher and Schuell, Kean, NH) for 20 hours at 15 V (initial current of 700 mA) using the method of Towbin et al.²² Remaining protein binding sites on the membrane were blocked with 5% BSA at 20 °C for two hours prior to incubation with MoAb diluted 1:400 in Tris-buffered saline pH 7.5 containing 0.2% gelatin at 20 °C for 18 hours with shaking. The membrane was washed in buffer, then incubated with peroxidase-conjugated sheep anti-rat IgG (Amersham) for 4 hours at 20 °C. Color development was with 4-chloro-1-naphthol (60 mg/100 mL) in Tris-buffered saline.

Flow cytometry. Antibody binding to CBA mouse cells was determined using a fluorescence-activated cell sorter (FACS 420, Becton Dickinson, Sunnyvale, CA). Cell suspensions were treated with hybridoma supernatant, washed twice with PBS, then stained with affinity-purified IgG mouse anti-rat IgG coupled to fluorescein. Stained cells were analyzed directly or fixed with 10% paraformaldehyde in PBS and stored at 4 °C prior to analysis.²³ Cell populations such as lymphocytes and monocyte/macrophage cells were electronically "gated" following positive identification in low angle ν 90° scatter graphs and fluorescence intensity profiles measured on these cell populations using logarithmic amplification.

Immune adherence assay. Immune adherence was determined using platelet-dependent agglutination of antibody-coated sheep erythrocytes (EA) in the presence of mouse complement. This assay has been described previously⁷ and erythrocyte agglutination shown to be dependent on platelets, complement, and antibody-coated indicator cells and to be inhibited by EDTA and heparin. Platelet-rich plasma was prepared from cardiac blood of F_1 mice collected into siliconized tubes containing trisodium citrate as an anticoagulant. After centrifugation at $200 \times g$ for ten minutes, platelet-rich plasma was removed with gentle stirring to increase platelet yield, and the remaining suspension centrifuged at $1,200 \times g$ for five minutes to produce PPP. PRP was diluted 1:4 in PBS prior to use (platelet concentration 3×10^8 /mL). Platelets were mixed with PBS, or antibody (25 μ L final volume) for 30 minutes prior to addition of EA (25 μ L, 1% v/v). EA were prepared by coating sheep erythrocytes (2% v/v) with subagglutinating concentrations of rabbit hemolysin (Wellcome Reagents, Beckenham, England) (1:1,600 dilution in PBS). Microtiter plates were agitated gently at 20-minute intervals and agglutination assessed at 60 to 90 minutes. Under these conditions, and using diluted platelet-rich plasma (1:4), no hemolysis of EA was observed over the period of assay.

Platelet aggregation. Cardiac blood was used to prepare PRP and PPP as described above. Aggregation studies were performed at 37 °C under continuous stirring in a Corning (Corning, NY) EEL-169 platelet aggregometer. PRP (400 μ L) was mixed with antiserum or hybridoma supernatant (50 μ L) and aggregation initiated by addition of 50 μ L of 10 mmol/L ADP in saline. 100% transmission was determined with PPP.

Platelet cytotoxicity. Sheep erythrocytes from defibrinated blood were washed in Alsever's solution and stored at 4 °C. Erythrocytes were labeled with ^{51}Cr Chromium,⁴ washed three times with PBS, and coated with subagglutinating concentrations of rabbit hemolysin

(1/400 to 1/800) (Wellcome) prior to use. CBA or F_1 platelets were purified from PRP and suspended in a 1:4 dilution of plasma from DBA mice (2 to 6×10^9 platelets/mL). Aliquots of this platelet suspension were incubated with control NS1 supernatant or hybridoma supernatant ($25 \mu\text{L}$) at 20°C for 30 minutes prior to addition of ^{51}Cr -labeled antibody-coated sheep erythrocytes (0.25% v/v, $50 \mu\text{L}$). Incubation was continued at 37°C for three hours with gentle agitation at 15-minute intervals. Radioactivity released was determined in a γ -counter following centrifugation at $1,000 \times g$ for five minutes to remove unlysed cells. Specific lysis was determined relative to controls lacking platelets or using heat inactivated plasma from DBA mice and complete release of radioactivity with plasma from CBA or F_1 mice.

RESULTS

Identification and characterization of Pgp-1 on platelets. The presence of Pgp-1 on mouse platelets is shown in Fig 1 where the titration curve of C71/26 MoAb is compared with that of several other MoAbs against platelet-cell-surface glycoproteins, some of which are known to be associated with cell-mediated cytotoxic reactions (Table 1). Similar results have also been obtained by radioimmunoassay and by indirect immunofluorescence (results not shown). Immunoprecipitation of mouse platelets radiolabeled with ^{125}I -iodide (Fig 2) or ^3H -sodium borohydride (Fig 3) with C71/26 MoAb against Pgp-1 resulted in a broad band of radioactivity of mol wt 87,000 to 100,000. This band appeared to be different from the β -subunit of LFA-1 which immunoprecipitated a sharper band at mol wt 97,000. Immunoclearance experiments and peptide mapping showed these two glycoproteins to be quite distinct. Antiserum against mouse peritoneal macrophages immunoprecipitated LFA-1 from ^3H -labeled mouse platelets and a broad band of radioactivity which appeared to include Pgp-1. In contrast, antiserum against mouse thymocytes immunoprecipitated

Fig 1. Binding of MoAbs against Pgp-1 and other functionally associated cell surface molecules to mouse platelets. Hybridoma supernatants C71/26 (Pgp-1), $\bullet$ — $\bullet$; C71/16 (LFA-1 β), ∇ — ∇ ; I41/14 (T200), Δ — Δ ; I21/7 (LFA-1 α), $\blacktriangle$ — $\blacktriangle$; and M1/70 (CR3), $\circ$ — $\circ$ were titrated against platelets using solid phase ELISA. Absorbance measurements (A490-410) were subtracted from controls using NS1 plasmacytoma culture supernatant.

Fig 2. Immunoprecipitation of Pgp-1 from mouse platelets. Platelets surface-labeled with ^{125}I were lysed with detergent and immunoprecipitated with C71/26 (lane 2) or I21/7 (lane 3). Immunoprecipitates were analyzed by SDS-polyacrylamide gel electrophoresis under reducing conditions and the gels autoradiographed. For comparison, ^{125}I -labeled proteins from the whole platelet lysate are shown in lane 1. The two most prominent bands are glycoproteins IIb and IIIa.

LFA-1, but not Pgp-1 from ^3H -labeled platelets. A nonspecific band at mol wt 150,000 was also observed in immunoprecipitates from ^3H -labeled platelets. Immunoblotting allowed direct comparison of Pgp-1 molecules on platelets, macrophages, and spleen cells (Fig 4). Platelets showed two Pgp-1 bands at mol wt 87,000 and 97,000 whereas peritoneal macrophages showed the 87,000 mol wt band and a prominent additional band at mol wt 82,000. A faint Pgp-1 band was also observed on spleen cells at mol wt 89,000. Pgp-1 was not observed on thymocytes or on a mast cell precursor line (P-cell), or on the nonhematopoietic tissues tested, which included liver, kidney, brain, and testis. In other immunoblotting experiments, neutrophils and bone marrow cells showed a strong Pgp-1 band whereas erythrocytes, erythroid precursor cells from the spleen of phenylhydrazine-treated mice, eosinophils from *M. corti*-infected mice, and skeletal muscle tissue were negative.

The relative abundance of Pgp-1 on peripheral blood monocytes is demonstrated in Fig 5. More than 97% of peripheral blood monocytes and peritoneal macrophages expressed Pgp-1, the mean relative fluorescence (MRF) being 7.0 and 7.5, respectively. In contrast, lymphocytes from peripheral blood and from spleen showed heterogeneous fluorescence intensity profiles, with 20% to 30% of cells fluorescence negative and 5% to 10% strongly fluores-

Antibody: NRS Mac-1 Pgp-1 LFA-1 ATS AMS Whole Lysate

Fig 3. Glycosylation of platelet Pgp-1. Platelets surface-labeled with ^3H -sodium borohydride were lysed with detergent and immunoprecipitated with 1, control rabbit serum; 2, M1/70; 3, C71/26; 4, I21/7; 5, antithymocyte serum; and 6, antimacrophage serum. Immunoprecipitates were analyzed by SDS-polyacrylamide gel electrophoresis under reducing conditions and the gel autoradiographed. Lane 7 shows ^3H -labeled proteins in the whole platelet lysate.

cence positive (MRF = 6.5 to 7.0). The majority of lymphocytes were weakly positive (MRF = 2.5 to 5.0). Lymphocytes from the peritoneal cavity showed more homogeneous expression of Pgp-1, with 96% fluorescence positive with an intermediate MRF of 5.5. Platelets were also shown to be fluorescence positive for Pgp-1 by flow cytometry, the right shift of the fluorescent intensity profile with associated peak symmetry indicating that all platelets expressed Pgp-1.

Functional associations of Pgp-1 on mouse platelets. The presence of Pgp-1 on mouse platelets, monocytes, macrophages, and neutrophils and on subpopulations of

Fig 5. Comparison of binding of C71/26 MoAb against Pgp-1 to lymphocytes, monocytes, and platelets. Pgp-1 on gated cell populations in peripheral blood leukocytes and peritoneal cells and on spleen cells and platelets was determined by flow cytometry. Control cells were treated with NS1 plasmacytoma supernatant. A reference bar is included in each fluorescence intensity profile for comparative purposes.

lymphocytes suggests a role in some common function. Initial investigations of the effect of the MoAb C71/26 against Pgp-1 on platelet aggregation induced by adenosine diphosphate (ADP) showed no significant effect. Rodent platelets however are known to be involved in immune adherence,² a function which is also shared with phagocytic cells and lymphocytes. Thus, MoAbs against Pgp-1, CR3, CR1, FcR2, T200, and LFA-1 were tested for their ability to inhibit platelet adherence to antibody-coated sheep erythrocytes in the presence of complement. Figure 6 shows that M1/70 against CR3 extensively inhibited platelet immune adherence whereas Dako-C3bR against human CR1 inhibited to a titer of 1:8. At the highest concentration of antibody

Fig 4. Immunoblotting of cell proteins with C71/26 MoAb against Pgp-1. Cells or washed tissue (0.5 μL packed volume equivalent) were solubilized in NP-40 buffer, electrophoresed on SDS-polyacrylamide gels, and transblotted onto nitrocellulose. Pgp-1 was detected with C71/26 MoAb, peroxidase-conjugated second antibody, and 4-chloro-1-naphthol.

Fig 6. Effect of MoAbs against Pgp-1 and other functionally-associated cell-surface molecules on platelet immune adherence. Platelet-rich plasma was diluted and incubated with antibody prior to the addition of opsonized erythrocytes. Inhibition of red cell agglutination is seen as a greatly reduced ability to form red cell buttons.

used, C71/26 against Pgp-1 inhibited aggregation. The possibility that this inhibition of immune adherence may have been caused by antibody-dependent agglutination of platelets was examined by phase contrast microscopy. The only antibody which caused significant platelet agglutination was C71/26, and this effect was only evident with undiluted hybridoma supernatant.

Another function held in common between most cells expressing Pgp-1 is antibody-dependent cell-mediated cytotoxicity involving complement. To test the involvement of Pgp-1, LFA-1, and CR3 in platelet cytotoxicity, a ^{51}Cr -release assay similar to that described by Soper and Winn⁴ was used. The characteristics of this assay and the effect of MoAbs against Pgp-1, LFA-1, and CR3 on complement-dependent platelet cytotoxicity are shown in Table 2. In five experiments platelet-dependent lysis of ^{51}Cr -labeled sheep erythrocytes varied between 14% and 94%. Specific lysis was determined relative to background release in the absence of platelets using C5-deficient plasma from DBA mice (Experiments 1 through 4) or in the presence of platelets using heat inactivated plasma from DBA mice (Experiment 5) and complete ^{51}Cr -release with plasma from CBA or F_1 mice. Under conditions where platelet agglutination was not observed, C71/26 against Pgp-1 inhibited lysis of antibody-coated erythrocytes by 44% to 100%. With either F_1 or CBA platelets, inhibition was greater under conditions which favored less complete target cell lysis. Other MoAbs against Pgp-1, 142/5, and IM7 also inhibited platelet cytotoxicity (Table 2, Experiments 2 and 5). In addition, 121/7 against LFA-1 α and C71/16 against LFA-1 β reproducibly inhibited platelet cytotoxicity, although two other MoAbs against different epitopes of LFA-1 α , that is, M17/5 and M17/4, showed little or no effect. Similarly, M1/70 against CR3 did not significantly affect platelet cytotoxicity. The possibility that platelet-bound antibodies activated and depleted complement components indirectly causing inhibition of platelet cytotoxicity is ruled out by the observation that complement-fixing MoAbs such as M17/5 (Experiment 3) and 9F6 (Experiment 5), which bound strongly to platelets,^{7,24} did not inhibit platelet cytotoxicity.

DISCUSSION

The polymorphic cell surface glycoprotein Pgp-1 was first described by Hughes and August²⁵ as a major antigenic component of mouse embryo 3T3 fibroblasts, but later was shown to be a constituent of myeloid and lymphoid cell membranes.^{8,26-28} We show here that Pgp-1 is also represented on purified mouse platelets and present evidence of a role for Pgp-1 in antibody-dependent cellular cytotoxicity mediated by platelets. In an enzyme-linked immunosorbent assay (ELISA), MoAbs against Pgp-1 and human glycoprotein IIb/IIIa showed high binding to mouse platelets relative to other MoAbs tested. Both the α - and β -subunits of LFA-1 and T200 were also present. These results confirm previous results which showed that EDU-3 cross-reacted with a small fraction of mouse platelets,²⁹ and that LFA-1⁷ and certain epitopes of the T200 family of cell surface glycoproteins³⁰ were also expressed on mouse platelets. Both immunoprecipitation and immunoblotting procedures indicated heterogeneity of the Pgp-1 molecule on platelets, immunoblotting resolving discrete molecular forms on both platelets and macrophages. A minor platelet protein of mol wt 180,000 detected by C71/26 MoAb by immunoblotting has not been identified, but may represent a precursor form of Pgp-1, possibly of cytoplasmic origin as it was not detected by surface-labeling procedures. The Pgp-1 glycoprotein on platelets did not correspond with any of the major surface-labeled glycoproteins (Figs 2 and 3) although possible identity with platelet glycoprotein IV³¹ is suggested by similar mol wts and by lack of mol wt shift following complete reduction (results not shown).

The distribution of Pgp-1 on mouse splenic lymphocytes (Fig 5) shows close similarity to previously published results²⁸ in which the majority of cells exhibited low relative fluorescence. However, we have detected a minor population (5% to 10%) of more brightly fluorescent lymphocytes in both splenic and peripheral blood. These results were supported by the immunoblotting studies which showed low levels of Pgp-1 on spleen cells relative to macrophages and platelets (Fig 4). Flow cytometry also indicated low relative fluorescence per platelet, a result which reflects the small surface area of the platelet compared to lymphocytes and macrophages.

Despite the isolation and biochemical and genetic characterization of Pgp-1,^{8,25-28,32,33} its function has remained elusive. The description of Pgp-1 on platelets provided a system in which to test several functional associations. Initial experiments indicated no effect of antibodies against Pgp-1 on platelet aggregation and a marginally significant inhibition of immune adherence of platelets to antibody-coated sheep erythrocytes in the presence of complement (Fig 6), an effect that correlated with antibody-induced platelet agglutination. That immune adherence is mediated through complement receptors is suggested by the fact that MoAbs against both CR3 (Mac-1) and human CR1 inhibited platelet-erythrocyte agglutination under conditions where no platelet agglutination was observed. Using C5-deficient plasma from DBA mice, platelets were shown to lyse antibody-coated sheep erythrocytes. Specific lysis varied between 14% to 94% and was determined relative to controls lacking platelets and to complete release via the complement cascade using plasma from F_1 or CBA mice. The reason specific lysis varied in different experiments is not fully understood, but possibly relates to the state of platelet activation in individual experiments, to the quality of the target erythrocytes, to the mouse strain used to prepare platelets, and to the nature and frequency of shaking which has been shown to influence platelet cytotoxicity.⁴ The experiments described in Table 2 have used purified CBA or (CBAXC57B1/6) F_1 platelets in the presence of C5-deficient plasma from DBA mice to effect cytotoxicity of antibody-coated erythrocytes. Platelets were washed prior to use so that plasma carryover was at least two orders of magnitude lower than that required to effect cytotoxicity by the complement cascade. Furthermore the presence of plasma from DBA mice is necessary to cause platelet-dependent cytotoxicity; omission of plasma or heat-

treatment of the plasma negates the killing effect. In some experiments we have observed cytotoxicity with PRP from DBA mice, but in general cytotoxicity is lower and the effect more variable than with CBA or F₁ platelets. Inhibition of platelet cytotoxicity with C71/26 MoAb against Pgp-1 was highly significant within each experiment, more extensive at low specific lysis with a particular mouse strain, and titratable (Table 2). Furthermore, the possibility that the inhibition of platelet cytotoxicity seen with C71/26 MoAb was caused by platelet agglutination by virtue of its IgM isotype was ruled out both visually and by using other Pgp-1 MoAbs of IgG2a and IgG2b isotypes (Table 2).²⁸ No significant effect of M1/70 MoAb against CR3 was observed. In contrast, MoAbs against LFA-1 produced variable inhibition of platelet cytotoxicity, I21/7 against the α -subunit and C71/16 against the β -subunit inhibiting specific lysis by 25% to 103%, M17/4 inhibiting by 21%, and M17/5 showing no inhibition. Thus, certain epitopes on both Pgp-1 and LFA-1 on platelets appear to be involved in or closely associated

with the cytolytic process. The variability of inhibition of cytotoxicity observed with MoAbs against LFA-1 has been observed previously with CTL-mediated killing in both human³⁴ and mouse^{10,35} studies. Inhibition of cytolysis appeared to be dependent on the target cell used³⁵ and no correlation of the effect of LFA-1 monoclonal antibodies on platelet cytotoxicity and CTL-mediated killing were evident. It will be of interest to determine the effect of MoAbs against Pgp-1 on other antibody-dependent cytotoxic events—for example, those involving macrophages and neutrophils, which have both been shown to express Pgp-1. Furthermore, it would also be of interest to investigate functionally human cells, which may also express Pgp-1.²⁸ In this context, human platelets have recently been shown to exert cytotoxic effects on tumor cells.³⁶

Cloning and Characterization of Platelet Factor 4 cDNA Derived From a Human Erythroleukemic Cell Line

By Mortimer Poncz, Saul Surrey, Paul LaRocco, Mitchell J. Weiss, Eric F. Rappaport, Theresa M. Conway, and Elias Schwartz

We report the isolation of a platelet factor 4 (PF4) cDNA clone from a λ gt11 expression cDNA library which was derived from a human erythroleukemic (HEL) cell line. The sequence of the DNA insert includes the 3'-untranslated region, the entire amino acid coding region for the mature PF4 protein, and a 5' region containing coding information for an additional 18 amino acids. In addition, supplemental genomic DNA sequencing shows that the full-length leader sequence is 30 amino acids long plus an initial methionine and codes for a hydrophobic signal-like sequence which is probably involved in transmembrane transport. A single species mRNA of approximately 800 nucleotides was detected on blots of HEL cell poly(A) + RNA using a labeled PF4 cDNA probe. The human PF4 leader sequence shares

some DNA, but no amino acid, homology with the 15 amino acids at the N-terminus of mature bovine PF4, suggesting rapid divergence in this region of PF4 between these two species. Sequence comparison of the coding regions of mature PF4 and γ IP-10, a protein induced in a variety of cells following treatment with γ -interferon, shows a corrected divergence of 76%. The divergence of a common ancestor protein into PF4 and γ IP-10 may have accompanied the development of sophisticated immune and coagulation systems in vertebrates. The availability of cDNA and genomic DNA information for these genes in other species will be useful in studying the evolution of the coagulation and immune systems.

Platelet factor 4 (PF4) is made in megakaryocytes and packaged into α granules for release during platelet activation.¹⁻⁴ PF4 strongly binds to heparin and related glycosaminoglycans.^{5,6} A major physiologic role of PF4 may be the neutralization of heparin-like molecules in the serum and on endothelial cell surfaces, thereby decreasing antithrombin III activity and allowing coagulation to proceed.⁷ PF4 also binds to platelet membranes, activating coagulation at low agonist concentrations⁸; acts as a chemotactic factor for neutrophils, monocytes, and fibroblasts^{9,10}; stimulates the release of histamines by basophils¹¹; and substitutes for fibronectin in the adherence and spreading of cells on surfaces in vitro.¹²

Human PF4 contains 70 amino acids and has four cysteine residues; these participate in the formation of intramolecular disulfide bonds.¹³⁻¹⁶ A larger precursor protein for PF4 in rabbits was suggested from analysis of pulse-labeled proteins from rabbit megakaryocytes; however, pulse-chase experiments were not consistent with a precursor-product relationship between the larger protein and PF4.⁴

Bovine PF4 is the only PF4 other than human for which an amino acid sequence has been determined.¹⁷ The bovine protein is 88 amino acids long, with 70% homology to human PF4 in the region of overlap. The most striking difference between the two is the presence of an additional 15 amino acids at the N-terminus of bovine PF4.

PF4 is a member of a family of small proteins that are released from cells after stimulation and act as secondary signals in the related processes of coagulation, inflammation, and tissue repair. PF4 shares amino acid sequence homology with β -thromboglobulin (β TG)¹⁸ and γ IP-10.¹⁹ β TG is also a megakaryocyte/platelet-specific protein which is stored in α granules. A comparison of human β TG and PF4¹⁸ shows correspondence at 42 of the 81 amino acid residues, with amino acid differences at another 11 residues that can be attributed to single-base replacements at the DNA level. The four cysteine residues occupy the same relative position in the two molecules. γ IP-10 is synthesized and released from several cell lines following γ -interferon stimulation. Over a 62 amino acid region, γ IP-10 and PF4 have 22 identical amino acids and 26 amino acids that can be accounted for by

single-base replacements at the DNA level. In addition, hydrophobic profiles and placement of cysteine residues are similar, suggesting evolution from a common precursor.

The study of the evolutionary relationships and functional roles of these small proteins would be enhanced by isolation of the genes for PF4 and β TG. The ability to isolate and study genes which are expressed only in megakaryocytes and platelets was hampered until recently by the difficulty of isolating sufficient mRNA to establish a cDNA library. The discovery that a human erythroleukemic (HEL) cell line expresses a number of megakaryocyte-like proteins as determined by electron microscopy and immunologic detection²⁰ prompted us to establish a cDNA expression library using mRNA from these cells. We now describe the isolation and characterization of a human PF4 cDNA clone from this library and present evidence for the existence of a PF4 precursor protein in humans. We also present new observations on sequence homology at the DNA and amino acid levels between human PF4, bovine PF4, and γ IP-10.

MATERIALS AND METHODS

Cell line and preparation of a cDNA expression library. The HEL cell line was kindly provided by P. Martin, Seattle.²¹ It was grown and induced with 1.25% (v/v) dimethylsulfoxide, and total

RNA was prepared using guanidinium thiocyanate (Fluka, Ronkonkoma, NY) and banding onto a cushion of cesium chloride.²² Total RNA was precipitated with ethanol at -70°C , and poly(A)⁺ RNA isolated by passage through an oligo-dT cellulose column (Collaborative Research, Inc, Bedford, MA). A cDNA library was constructed in λgt_{11} , as described,²³ except that double-stranded cDNAs were fractionated by size twice on Sepharose CL4B prior to cloning to enrich for molecules greater than 300 bp in length. The HEL cell library contained 1.5×10^6 recombinants, with an average insert size of 1.7 ± 0.8 kb.

Library screening. The library was screened with a commercial human PF4 antibody prepared in goats (Atlantic Antibodies, Scarborough, ME).²⁴ Positive plaques were detected, isolated, and purified using a biotinylated rabbit anti-goat antibody, which was then coupled to an avidin-biotin-horseradish peroxidase complex (Vector Laboratories, Inc, Burlingame, CA), with detection of complexes facilitated by localization of bound peroxidase using the chromogen 4-chloro-1-naphthol.

Characterization of positive plaques. Phage DNA was purified from positive plaques, digested with *EcoRI* (Bethesda Research Laboratories, Gaithersburg, MD, (BRL)), and the insert isolated by electroelution (International Biotechnologies, Inc, New Haven, CT) following size fractionation on agarose gels. The insert was mixed with 200 ng of *EcoRI*-digested RF M13mp19 phage, precipitated in ethanol, pelleted, ligated, and transfected into *E. coli* JM107.²⁵ Double-stranded DNA was purified from clear plaques and characterized on gels following *EcoRI* digestion. Single-stranded DNA was also prepared, and phage with inserts in opposite orientation was identified following gel analysis of S1-nuclease-resistant heteroduplexes. We determined the DNA sequence of single-stranded DNA from phage harboring the insert in the two different orientations by the dideoxy sequencing technique using the universal M13 primer (BRL).^{26,27}

Isolation of additional human cDNA and genomic PF4 clones. Double-stranded PF4 insert was labeled with $\alpha\text{-}^{32}\text{P}$ -dCTP (Amersham, Arlington Heights, IL) using *E. coli* DNA polymerase (BRL) and calf thymus DNA primers.²⁸ This probe was used to rescreen the HEL cell cDNA library as well as a human genomic DNA library which was constructed by partial *Sau3A* digestion of genomic DNA followed by cloning into EMBL 3A as previously described.^{29,30} Positive clones were plaque purified, and appropriate inserts subcloned into M13 bacteriophage as described above.

Characterization of PF4 mRNA from HEL cells. ^{32}P -labeled PF4 cDNA probe was also hybridized to Nytran (Schleicher and Schuell, Keene, NH) blots of agarose gel-fractionated, formaldehyde-denatured HEL cell poly(A)⁺ RNA.²⁸ RNA size was determined relative to ^{32}P -labeled DNA markers made by end-labeling Hae III digests of ϕX174 phage (BRL).

Computer analysis. PF4 and $\gamma\text{IP-10}$ cDNAs were analyzed for DNA homology with the ALIGN program on BIONET.³¹ In addition, the two proteins were compared by the FASTP program³² which aligns sequences on the basis of an amino acid replaceability matrix, giving higher scores to those replacements which occur frequently in evolution.

RESULTS

Isolation and characterization of a PF4 cDNA clone. Two positive clones, each containing approximately 400-bp inserts, were found while screening 1.2×10^5 recombinants. One insert was isolated, subcloned into M13, and the DNA sequence determined (Fig 1). This 409-bp insert contains a 54-bp 5'-leader sequence followed by the entire coding sequence of PF4, an in-frame termination codon (TAG), a

Fig 1. DNA sequence of human PF4 cDNA. The sequence shown is derived mainly from the 409 bp PF4 cDNA clone. The 5'-untranslated region sequence and the first 35 nucleotides of the coding region were obtained from a PF4 genomic DNA clone. The amino acid sequence for the leader sequence and mature PF4 are included. The arrowhead indicates the N-terminus of mature PF4. The DNA sequence for the coding region is in capital letters, and the partial 5'- and complete 3'-untranslated regions are shown in lower-case letters. Two potential polyadenylation signal sequences are underlined.

126-bp 3'-untranslated region containing two potential polyadenylation signals, and an oligo-dA tail of 16 adenosine residues located 11 bp 3' to the first polyadenylation sequence. The 54-bp 5' leader contains an open reading frame for 18 amino acids and no in-frame chain-initiating sequence for methionine (ATG), indicating that human PF4 is derived by proteolytic processing from a precursor with at least 18 additional amino acids at the N-terminus.

Other PF4 cDNA clones isolated from the expression library provided no additional 5' DNA sequence information. We therefore determined the remaining leader sequence from partial sequencing of a human genomic PF4 clone. The full-length leader is 30 amino acids long, preceded by a methionine residue and a 5'-noncoding sequence which contains a consensus sequence for a translational initiation site.³³ The 31-amino-acid leader sequence contains a 17-amino-acid hydrophobic core.

The size of PF4 mRNA was estimated to be approximately 800 nucleotides (n) (Fig 2), which is 350 n larger than the sequence shown in Fig 1, suggesting (assuming a poly A tail of 100 to 200 n) a 5'-untranslated region of approximately 200 n.

Abundance of PF4 mRNA in HEL cells. A variety of methods was used to estimate the abundance of PF4 mRNA in HEL cells. Two PF4 cDNA clones were detected from 1.2×10^5 recombinants using the antibody screen. Since only one of six possible reading frames leads to proper protein expression in this system, the abundance of PF4 mRNA is estimated at 0.01% ($12/[1.2 \times 10^5]$). Visual comparisons of lighter exposures of the autoradiograph in Fig 2 and other autoradiographs of known amounts of PF4 cDNA insert and mRNA blotted to Nytran (data not shown) suggest again

Fig 2. Size of PF4 mRNA in HEL cells. Autoradiograph of a nitrocellulose blot hybridized to labeled PF4 insert. Lane 1 = 0.8 μ g HEL cell poly A (+) RNA. Lane 2 = 10 pg of the 408-bp PF4 insert. Lane 3 = ^{32} P end-labeled ϕ X Hae III DNA markers.

that the frequency for PF4 mRNA in HEL cell mRNA is $\approx 0.01\%$.

Comparison between human PF4, bovine PF4, and human γ IP-10. The amino acid sequence of bovine PF4 is homologous to human PF4 over much of the molecule; however, it differs by the addition of 15 amino acids at its N-terminus that are not present in human PF4.¹⁷ Comparing the human PF4 leader with the amino acid residues at the N-terminus and the deduced DNA coding sequence of bovine PF4 reveals sequence similarity at the DNA, but not the amino acid level (Fig 3). There is a 30-bp region of 63% DNA homology, underlined in Fig 3. While DNA homology suggests that the N-terminus of bovine PF4 and the leader of human PF4 may be related, no significant amino acid homology exists, apparently secondary to nucleotide deletions and insertions.

A previous study¹⁹ using the FASTP protein analysis program³² reported extensive homology between the mature human PF4 and γ IP-10. Using the same program, we compared the human PF4 precursor protein sequence determined from our cDNA clone with the protein γ IP-10, and

found the same match previously reported.¹⁹ No new N-termini amino acid homology was detected.

Human PF4 and γ IP-10 cDNA sequences were also compared at the DNA level using the ALIGN program.³¹ DNA sequence similarity was found at the 3' end of the coding regions. This similarity begins at the 19th amino acid (valine) of the mature PF4 and the 18th amino acid (valine) of the processed γ IP-10 and extends for approximately 100 bp downstream, depending on the parameter settings (data not shown). A comparison of the 3'-untranslated regions revealed no further DNA sequence similarity. A comparison of the leader regions of the two proteins reveals a 22-bp region (underlined in Fig 3) with 73% similarity, suggesting that this region of the two proteins may have evolved from a common sequence. Further studies of these genes in other species should be helpful in resolving the evolutionary relationship between the leader regions of these proteins.

Analysis of the DNA sequences coding for the mature PF4 and γ IP-10 reveals 43% sequence similarity, with 47% similarity for the first nucleotide of the coding triplets, 56% for the second, and 25% for the third. Divergence for nonsynonymous substitutions (those causing amino acid changes) between these genes was 76%, including a correction for multiple substitutions at the same nucleotide.³⁵

DISCUSSION

The PF4 cDNA is the first probe isolated for a protein whose expression is restricted to the megakaryocyte/platelet lineage. These studies confirm immunologic and morphologic data that HEL cells express megakaryocytic/platelet-like properties.²⁰ We are presently pursuing the isolation and characterization of additional cDNA and genomic clones for platelet-specific proteins in order to better understand their biological properties and coordinated expression during megakaryocyte development.

Attempts to understand megakaryocytic development from an undifferentiated stem cell have been limited to morphologic, cytochemical, and immunologic studies. The PF4 cDNA probe will now facilitate detection of changes at the DNA and transcriptional levels prior to accumulation of protein during normal megakaryocyte development, as well as in leukemias and myelofibrosis syndromes characterized by aberrant expression of megakaryocyte-like cells.

Our results demonstrate the presence of a human PF4 leader sequence of 30 amino acids whose structure resembles other known signal sequences involved in transmembrane transport.³⁴ These results suggest that the PF4 leader may be

Fig 3. Similarity between the leader sequence for human PF4, the N-terminus of bovine PF4, and the leader sequence of γ IP-10. The bovine PF4 DNA sequence was deduced from its amino acid sequence. U = purine, Y = pyrimidine, and N = any nucleotide. A line represents identity, a dashed line represents potential identity in cases where ambiguity exists in the triplet coding sequence. A 30-n region of similarity between human and bovine PF4 is overlined, and a 22-n region of similarity with γ IP-10 is underlined. Arrowhead indicates cleavage sites for the generation of the mature protein.

involved in packaging PF4 into α granules, followed by removal by proteolysis. Leader sequences of other proteins which are targeted to specific subcellular organelles have been shown to be critical for the proper localization of these proteins. The PF4 leader sequence differs from leader sequences of mitochondrial proteins³⁶ by lacking arginine or lysine residues thought to be critical for targeting to the mitochondrion. Comparison of human PF4 leader with the leader sequence of the γ chain of fibrinogen³⁷ also reveals neither amino acid nor hydrophobic regions of homology. The γ chain of fibrinogen is made in the liver, but is also thought to be synthesized in megakaryocytes and stored in α granules.² The leader sequence for this protein contains 26 amino acids, consisting of 12 hydrophilic residues and no long stretch of hydrophobic amino acids. Whether this leader sequence is also involved in targeting γ -fibrinogen to α granules is not known. Perhaps an alternative leader sequence is utilized for γ -fibrinogen synthesized in the megakaryocyte. Determination of leader sequences for other platelet proteins destined for localization in α granules should further our understanding of the relationship between leader sequence and cellular localization. The N-termini of human and bovine PF4 appear to have evolved from a common DNA sequence, yet code for divergent amino acid sequences, with the bovine N-terminus lacking the hydrophobic core that is characteristic of many signal sequences. Ultrastructural studies show that bovine platelets lack a cytoplasmic canalicular system,³⁸ and the sequence differences between PF4 in these two species may possibly be a reflection of basic differences in membrane organization requiring different modes of PF4 transport and release.

It appears that the three human proteins, PF4, β TG,³⁹ and γ IP-10, are generated by cleavage at comparable sites in

their precursors, suggesting divergence from a primordial gene. Since many genes appear to have functional subunits divided into separate exons,^{40,41} we suggest that the cleavage site also represents the boundary of two genomic exons, one coding for the leader and the other for the small signal protein. Preliminary sequence analysis of our genomic PF4 clone suggests that this is the case for human PF4.

Comparison of DNA sequences coding for mature PF4 and γ IP-10 reveals significant divergence. The rate of nonsynonymous divergence for mammalian genes varies considerably, ranging from 0.004×10^{-9} to 2.80×10^{-9} substitutions per site per year,⁴² and also varies among different species⁴³ and in different evolutionary epochs.⁴⁴ Therefore, the actual time of divergence can only be estimated for the PF4 family of genes. It is of interest that interferon-like substances have only been detected in vertebrates, whose divergence from invertebrates is estimated to have occurred approximately 500 million years ago,⁴⁵ equivalent to a nonsynonymous rate of divergence of 1.52×10^{-9} for PF4 and γ IP-10. The divergence of a primordial protein into PF4 and γ IP-10 may have accompanied the development of sophisticated immune and coagulation systems in vertebrates. The availability of cDNA and genomic probes for these genes in other species will be useful in studying the evolution of the coagulation and immune systems.

ACKNOWLEDGMENT

Steady State Levels of Factor X mRNA in Liver and Hep G2 Cells

By Bruce R. Bahnak, Richard Howk, James H. Morrissey, George A. Ricca, Thomas S. Edgington, Michael C. Jaye, William W. Drohan, and Daryl S. Fair

In order to examine the control of human factor X biosynthesis we have molecularly cloned the cDNA and investigated the expression of the Factor X gene. A recombinant clone of approximately 1100 base pairs in length containing the sequence of factor X was identified in a λ gt11 human liver cDNA library by screening with polyclonal antibodies. One plaque was selected and confirmed for specificity with a mixture of five factor X specific monoclonal antibodies (MoAbs). A partial nucleic acid sequence of the 5' end of the cDNA corresponded to the described amino acid sequence between residues 41 and 56 of the light chain of factor X. Northern blot analysis of RNA from human liver and the hepatoma cell line, Hep G2, identified the factor X mRNA as a single molecular species of approximately 1700

bases. Cell lines which do not secrete factor X did not contain factor X mRNA indicating restriction of transcription to hepatocytes. Slot-blot hybridization analysis of factor X and actin mRNA demonstrated no change in the levels of total or specific factor X mRNA in Hep G2 cells following treatment with warfarin or vitamin K. We conclude that modulation of factor X production by these drugs, known to influence γ -carboxylation and total factor X secretion by these cells, is mediated by changes in posttranscriptional events rather than by effects on the steady state levels of factor X mRNA.

THE VITAMIN K-DEPENDENT coagulation proteins (factors VII, IX, and X, prothrombin, and proteins C and S) in human plasma are a family of molecules that are characterized by amino acid sequence homology and by unique γ -carboxyglutamic acid (gla) residues located in the amino-terminal domain.^{1,2} These gla residues, which are necessary for function resulting from calcium and phospholipid binding and conformational ordering of the proteins, are formed by a posttranslational modification step in which CO₂ is added to selected glutamic acids. The process also requires O₂, vitamin K, and the carboxylating enzyme system (carboxylase/reductase).^{2,3} Warfarin inhibits the vitamin K epoxide reductase which catalyzes the conversion of vitamin K, 2,3-epoxide to vitamin K.^{2,3} Administration of this drug to individuals decreases the enzymatic activity and concentration of all known vitamin K-dependent proteins.⁴⁻⁹ Vitamin K and warfarin have also been observed to modulate the levels of γ -carboxylated coagulation proteins secreted into the media from cultured cells derived from human and

rat hepatomas.¹⁰⁻¹² Decreased secretion of these proteins in response to warfarin treatment may be attributed either to a decrease in the rate of synthesis or to an increase in catabolic rate of the resulting partially modified proteins. Previous results from our laboratory suggest that the effect of warfarin on prothrombin and factor X levels is probably on synthesis.¹² Vitamin K may reverse this by increasing the rate of secretion from intracellular pools, as seen with rat prothrombin.¹⁰ Alterations in the rate of synthesis (transcription or translation), secretion, and turnover have been suggested as potential mechanisms responsible for changes in the concentration of proteins of this family in response to warfarin or vitamin K.¹⁰⁻¹³

Factor X is a 59,000 mol wt two-chain glycoprotein with a heavy (42,000) and a disulfide-coupled light (17,000) chain.^{14,15} The light chain contains 12 gla residues, and the heavy chain contains the active site. Studies using rat hepatocytes and rat and human hepatoma cells have indicated that factor X is synthesized as a single chain molecule by the liver.^{12,13,16} Analyses of cDNA clones from bovine and human liver libraries indicate that the factor X gene is transcribed as a single mRNA species consistent with the protein synthesis studies.¹⁷⁻¹⁹

The human hepatoma cell line (Hep G2) produces a variety of plasma proteins²⁰ including most of the vitamin K-dependent protein molecules.^{12,21} These proteins are rapidly secreted by the cell and resemble their plasma protein counterparts structurally, immunologically, and functionally.^{11,12,21} Further this cell line responds to warfarin and vitamin K by modulating the activity and concentration of the gamma carboxylated proteins.^{12,21} Decreased levels of prothrombin were noted 24 hours after exposure to warfarin, which was attributed to a reduced synthetic rate.¹² Decreased levels of factor X and the other vitamin K-dependent factors can be shown after they accumulate during a more prolonged culture period.^{12,21} One possible explanation for these observations would be an alteration in the transcriptional rate of the genes encoding these proteins. We have identified a partial cDNA recombinant clone for factor X from a λ gt11 expression library and have used it as a probe to characterize factor X mRNA in the Hep G2 cell line and human liver. Slot-blot analysis was used to investigate

the effects of vitamin K and warfarin on the expression of the factor X gene in Hep G2 cells by measuring the steady state levels of factor X mRNA.

MATERIALS AND METHODS

Materials. The human hepatoma cell line Hep G2 was provided and characterized by Drs Barbara B. Knowles and David P. Aden of the Wistar Institute, Philadelphia.²⁰ The cDNA probe for human cytoplasmic actin was kindly provided by Dr Elaine Fuchs of the University of Chicago.²²

Vitamin K (Aqua Mephyton) was obtained from Merck Sharp & Dohme (West Point, Pa). Restriction enzymes were from International Biotechnologies, Inc. (New Haven, Conn), and DNase I from Promega Biotec (Madison, Wis). Guanidinium isothiocyanate was purchased from Fluka Chemical Corp (Hauptpauge, NY), hydroxystilbamidine isothionate (HBI) was from Merril National Labs (Cincinnati, Ohio), and cesium trifluoroacetate (CsTFA) was from Pharmacia Fine Chemicals (Piscataway, NJ). Nucleic acid grade phenol, agarose, and formamide were obtained from Bethesda Research Laboratories (Bethesda, Md). Glyoxal was from Eastman Kodak Co. (Rochester, NY), and methyl mercury hydroxide from Alfa Products (Danvers, Mass). Polyadenylic acid and salmon sperm DNA were purchased from P.L. Biochemicals (Milwaukee). Quick-seal centrifuge tubes were purchased from Beckman Instruments, Inc (Palo Alto, Calif). Nitrocellulose and slot-blot apparatus (Minifold II) were purchased from Schleicher and Schuell, Inc (Keene, NH). Other enzymes and reagents were obtained from Sigma Chemical Co (St. Louis, Mo). Radioactive isotopes were from Amersham Co (Arlington Heights, Ill).

Cell culture. The effects of vitamin K and warfarin on the levels of factor X mRNA in the Hep G2 cell were investigated using 3×3 fixed factor analyses of variance without replication.²³ Conditions for growing and maintaining Hep G2 cells in culture were as described.¹² For experimental studies T-75 flasks were seeded with 1×10^6 cells and grown for seven days in Eagle's minimal essential media (MEM) and 10% heat-inactivated fetal calf serum (FCS). The cultures were washed and incubated approximately 30 minutes in serum-free MEM. The media was replaced with 12 mL of MEM (control) or in MEM supplemented with 10 μ g/mL vitamin K or 1 μ g/mL of the warfarin derivative, 3 (α -acetylbenzyl)-4-hydroxycoumarin. After the first 24-hour incubation, the cultures were washed and incubated with serum-free MEM as described above. One flask from each treatment group received media, media supplemented with vitamin K, or media with warfarin, after which the cells were incubated another 24 hours. The cells were then harvested, and total RNA isolated as described below.

Cloning of factor X cDNA. A cDNA library was constructed from mRNA isolated from adult human liver in the direct expression vector λ gt11 essentially as described.²⁴⁻²⁸ Poly(A)⁺ RNA was isolated and cDNA synthesized essentially as described by Buell et al.²⁴ and Wicken et al.²⁵ The cDNA was made blunt ended by incubation with S1 nuclease²⁶ and the Klenow fragment of DNA polymerase I.²⁷ The cDNA was then methylated with *Eco*RI methylase followed by ligation of *Eco*RI linkers and *Eco*RI digestion. After size fractionation to yield cDNA greater than 1 kb, the cDNA was ligated into *Eco*RI digested and phosphatase-treated λ gt11.²⁸ Approximately 300,000 λ gt11 recombinant phage plaques on *E. coli* Y 1090²⁸ were screened with the IgG fraction of rabbit polyclonal antibody against factor X² and antibody reactions were detected by using horseradish peroxidase-labeled second antibody. After purification, the isolates were screened with a mixture of five factor X-specific mouse MoAbs.²⁹ An independently isolated plaque containing a recombinant phage whose fusion polypeptide reacted with rabbit anti-human ferritin (M. Jaye, unpublished data) was used as control. The cDNA

insert was excised using a combination of restriction enzymes *Eco*RI and *Pvu*II and subcloned into these sites in pBR322. (The recombinant plasmid was referred to as pDH-1.) The cDNA insert was also subcloned between *Eco*RI and *Hinc*II sites of M13mp11. The recombinant phage was isolated and subjected to nucleic acid sequence analysis as described.³⁰ Isolation and characterization of the actin cDNA clone has been previously reported.²²

Isolation of RNA. For RNA isolation sterile disposable plasticware and, when needed, dry heat sterilized glassware were used. When appropriate, stock solutions were treated with 0.1% diethylpyrocarbonate and autoclaved. For Northern blot analysis RNA from tissues and large volume tissue culture was isolated by two methods. Method I was a modification of guanidinium isothiocyanate method,³¹ and method II involved centrifugation through CsTFA. For both methods cells were washed in ice cold 0.15 mol/L NaCl + 1.5 mmol/L HBI and placed on ice. The cells were harvested in 25 mmol/L sodium citrate, pH = 7.0, 0.5% Sarkosyl, 0.1 mol/L 2-mercaptoethanol, 5.6 mol/L guanidinium isothiocyanate. Approximately 15 mL of this solution was used for 10 T-175 flasks. From this point Method I was essentially as described.³¹

Method II involved layering 7 to 8 mL of the guanidinium isothiocyanate lysate of the cells on top of 3 mL of CsTFA ($d = 1.6$ g/mL) in 0.1 mol/L Tris-HCl, 0.1 mol/L KCl, 1 mmol/L EDTA (pH 8.0) in Beckman 16 $\times$ 76 mm Quick-seal centrifuge tubes. After centrifugation for 24 hours in a Ti-50 rotor at $100,000 \times g$, the supernatants were removed, and the pellets and sides of the tube were washed with 3 mL of 6 mol/L guanidine-HCl, 25 mmol/L sodium citrate, and 10 mmol/L 2-mercaptoethanol (pH 7.0). Approximately four pellets were dissolved in 3 mL of this solution and transferred to a clean tube, in which the RNA was precipitated with 2.2 volumes of cold 100% ethanol. The precipitate was washed twice with 70% ethanol, dissolved in RNase-free H₂O, and stored at -70°C . Polyadenylated mRNA was separated from other RNA species by binding to oligo(dT)-cellulose as described.³²

For slot-blot analysis, culture medium was removed from the cells, and the cells were harvested with 3.0 mL of 0.05% (w/v) trypsin and 0.5 mmol/L EDTA in MEM media. The trypsin digestion was stopped with 8 mL of ice cold MEM + 10% FCS, and 1 mL samples were removed for whole cell counts. The cells were centrifuged at $1500 \times g$, washed in ice cold 0.15 mol/L NaCl, 1.5 mmol/L HBI, 0.5 mmol/L aurointricarboxylic acid, pH 7.0, and transferred to microcentrifuge tubes. Three hundred microliters of proteinase K buffer (0.1 mol/L Tris-HCl, 10 mmol/L EDTA, 0.15 mol/L NaCl, 1% SDS; pH 7.5) was added, and the DNA from the lysed cells was sheared by passage through a 22-gauge needle. Proteinase K was added (300 μ g/mL) to each tube and incubated at 37°C for 45 minutes. Protein was removed by phenol:chloroform extraction, the organic phase reextracted with 200 μ L of 20 mmol/L Tris-HCl, 2 mmol/L EDTA, 0.1% SDS, pH 7.4. The pooled aqueous phases were extracted with chloroform followed by ethanol precipitation. The precipitated nucleic acids were dissolved in 80 μ L H₂O, made 40 mmol/L Tris-HCl, 10 mmol/L NaCl, 8 mmol/L MgCl₂, pH 7.9 and 10 U (10 μ L) of RNase-free DNase I and incubated 45 minutes at 37°C . DNase I was chloroform extracted, and the RNA concentrated by ethanol precipitation in 0.25 mol/L sodium acetate, pH 5.2. The precipitate was dissolved in RNase-free H₂O and the absorbance at 260 nm and 280 nm measured. If the $A_{260\text{nm}}/A_{280\text{nm}}$ ratio was less than 1.95, the samples were treated with DNase I until the ratio approached 2.0. The extent of the enzymatic digestions was tested by subjecting samples to RNase digestion.

Northern blot analyses. Northern hybridizations were done essentially as described.^{27,33} RNA samples were denatured with 1.0 mol/L glyoxal or 12.5 mmol/L methyl mercury hydroxide and electrophoresed in 1.2% horizontal agarose gels. After electrophoresis, gels were soaked 20 to 30 minutes in 10 mmol/L sodium

phosphate, pH 6.5, and the RNA transferred for 15 to 20 hours to nitrocellulose presoaked in $20 \times$ standard saline citrate (SSC = 0.15 mol/L NaCl, 0.015 mol/L trisodium citrate, pH 7.0). After transfer, the nitrocellulose was removed, air dried, and then baked at 70°C to 80°C in vacuo for two hours. The nitrocellulose was prehybridized 24 hours at 42°C in a solution containing $5 \times$ SSC, 50% formamide, $5 \times$ Denhardt's solution (1% Ficoll, 1% polyvinylpyrrolidone, 1% bovine serum albumin) and 100 $\mu\text{g}/\text{mL}$ denatured salmon sperm DNA.

The probes for hybridization reactions were made from nick translation of the pBR322 plasmid containing the subcloned factor X or actin cDNA insert.²⁷ The specific radioactivities of the probes varied from 5 to 50×10^7 cpm/ μg . Unincorporated nucleotides were removed by ethanol precipitation in the presence of 0.4 mol/L ammonium acetate, pH 5.2. The precipitated probes were boiled in 40 μL containing 1 mg/mL solution denatured salmon sperm DNA for ten minutes and cooled on ice. The denatured probes were added to a solution of the same composition as the prehybridizing solution plus 0.1% sodium pyrophosphate and 200 $\mu\text{g}/\text{mL}$ polyadenylic acid. The factor X probe was diluted to 1×10^7 cpm/mL and actin probe was diluted to 1×10^6 cpm/mL for hybridization reactions. Approximately 16 μL of probe was used per cm^2 of nitrocellulose paper. Hybridization was performed for 48 hours at 42°C . After incubation, the nitrocellulose was washed for five minutes in $2 \times$ SSC, 0.1% SDS at 65°C and three 30-minute washes in the same solution followed by three 30-minute washes in $0.2 \times$ SSC, 0.1% SDS. The nitrocellulose was air dried, and the hybridization reactions detected by autoradiography.

For slot-blot analysis appropriate concentrations of the RNA samples were made $10 \times$ SSC and denatured in 8% formaldehyde by heating at 65°C for 10 minutes. The samples were cooled to ambient temperature and diluted in $10 \times$ SSC so that the appropriate amount of RNA could be applied in 100 μL aliquots to nitrocellulose paper (0.45 μm) previously wetted in H_2O and presoaked in $20 \times$ SSC. The procedures for baking, hybridization, and washing of the nitrocellulose were as described above. The autoradiographs were quantitated by scanning with a laser densitometer (Zeineh soft laser scanning densitometer, Biomed Instruments, Inc, Chicago).

RESULTS

Four cDNA clones positive for factor X were detected from screening 300,000 plaques of a human liver cDNA expression library with rabbit anti-factor X antibody. After three cycles of plaque purification, one plaque was picked for further analysis. This clone showed a positive reaction when exposed to a mixture of five factor X-specific MoAbs, while the negative control plaques (ferritin cDNA clones) did not. The cDNA insert from this clone was excised with *Eco*R1 and *Pvu*II and found to be approximately 1100 bp long. Fig 1 shows a partial nucleotide sequence from the 5' end of the cDNA along with the deduced amino acid sequence and a previously published amino acid sequence for the light chain

Fig 1. Partial nucleotide sequence of human factor X cDNA (A). The predicted amino acid sequence (B) and the published sequence (C) are also shown beginning with residue 41. Numbers above line A indicate the nucleotide number of the isolated factor X clone, while numbers below line C represent the established amino acid sequence number.

of factor X.³⁴ The nucleotide sequence is identical to that reported earlier¹⁹ and corresponds to amino acid residues 41 to 56 of the light chain of factor X indicating that this cDNA clone represents a bona fide factor X cDNA which includes portions of both the light and heavy chains.

RNA was isolated from tissue using the guanidinium isothiocyanate technique (Method I).³¹ This and centrifugation through CsTFA (Method II) were used to isolate RNA from cells in culture, and both methods gave RNA with $A_{260\text{nm}}/A_{280\text{nm}}$ absorbance ratios nearly 2.0. Agarose gel electrophoresis demonstrated no detectable degradation of 28S and 18S ribosomal RNAs. Poly (A)⁺ RNA isolated from all samples of total RNA behaved similarly in in vitro translation assays and in cDNA synthesis. Nevertheless, controlled experiments showed that Method II yielded at least 5-fold more RNA than Method I ($\sim 116 \mu\text{g}/10^7$ cells v $20 \mu\text{g}/10^7$ cells) for cell culture samples. Presumably the difference in yields results from the single step isolation of Method II compared to multiple ethanol precipitations required in Method I. We found that pelleting RNA through CsTFA instead of isopycnic banding³⁵ of the nucleic acids required shorter centrifugation times and that pellets were easier to recover than by separating banded nucleic acids.

The size and number of mRNA species encoding factor X was examined using Northern blot analyses with RNA from the Hep G2 cell line, from human liver, and from a human breast tumor cell line (BT-20), which does not secrete factor X. Hybridizations of various concentrations of RNA from the Hep G2 cell line with the factor X nick-translated probe demonstrated a single mRNA species of 1700 bases (Fig 2, left panel). Northern blots of Poly (A)⁺ RNA from BT-20 cells as well as total RNA from liver and Hep G2 cells indicated that the factor X probe hybridized with only one mRNA size of 1700 bases in RNA from both liver and Hep G2 cells (Fig 2, right panel). The factor X probe did not hybridize with RNA from the breast tumor cell line, human

Fig 2. Northern-blot analysis of RNA from human liver and the Hep G2 and BT-20 cell lines. RNA was denatured in either glyoxal (lanes 1 through 3) or methyl mercury hydroxide (lanes 4 through 6) and electrophoresed in 1.2% agarose gels as described^{27,33} and explained in methods. Recombinant plasmid pDH-1, containing a 1.1-kb factor X cDNA insert, was nick-translated and used as the hybridization probe. (Lanes 1 through 3) 5, 7.5, 10 μg of total Hep G2 RNA; (lane 4) 2.5 μg Poly (A)⁺ mRNA from the BT-20 cell line; (lane 5) 7.5 μg liver total RNA; (lane 6) 7.5 μg Hep G2 total RNA.

kidney total RNA, or poly (A)⁺ from a human cervical carcinoma cell line (Me-180) (data not shown) indicating the restriction of factor X gene expression to hepatocytes.

Total RNA for slot-blot analysis was rapidly isolated from numerous small tissue culture samples by Method II. The time from cell harvest to blotting of RNA samples was as rapid as two days with a number of convenient stopping places in the procedure. It was critical to measure the $A_{260\text{nm}}/A_{280\text{nm}}$ ratio after DNase digestion to make sure the enzyme reaction was complete, because DNA contamination interfered with accurate quantitation of mRNA. Samples that were not DNase digested but were subjected to RNase gave strong hybridization signals indicating DNA contamination of the total RNA preparation (data not shown). When samples exhibiting high $A_{260\text{nm}}/A_{280\text{nm}}$ absorbance ratios were subjected to RNase A digestion, no hybridization was observed, indicating that the DNase digestion was complete. Usually 10 units of DNase were required to digest the DNA from approximately 3×10^6 cells and reflected an increase of the $A_{260\text{nm}}/A_{280\text{nm}}$ ratio from around 1.8 to greater than 1.95. Increasing the enzyme concentration or incubation time did not eliminate the need for an occasional second DNase digestion, suggesting that an enzyme inhibitor remaining from previous RNA purification steps is more efficiently removed by a second chloroform extraction. We attempted to use unfractionated cytoplasmic samples developed for dot-blots.³⁶ When it was necessary to blot high concentrations of RNA, we found it difficult to quantitatively transfer the RNA present in the cytoplasmic samples due to the limited surface area of the nitrocellulose membrane in the slot-blot apparatus. We observed that transfer was quantitative up to 8 μg of RNA and that binding was sensitive to RNase.

To determine if the warfarin- and vitamin K-modulated differences in synthesis and secretion of vitamin K-dependent proteins resulted from altered steady state levels of mRNA, we employed quantitative slot-blot analyses. Twelve seven-day-old Hep G2 cultures were washed with serum-free medium and divided into three groups which received either

medium alone or medium containing warfarin or vitamin K. After 24 hours, one flask from each group was removed and processed for cell number determination and RNA isolation. With the nine remaining flasks, subgroups of three flasks that were initially treated with vitamin K, warfarin, or media alone were distributed so that a sample from each group received either the same treatment or one of the other two treatments. After an additional 24 hours of culture, all the flasks were harvested, cell number determined, and RNA isolated. The results from these combinations were then subjected to analyses of variance to determine if any trends developed due to vitamin K or warfarin treatment. Total protein and DNA synthesis in Hep G2 cells are unaffected by warfarin and vitamin K (Bahnak and Fair, unpublished). We used hybridization to an actin cDNA clone and normalization of factor X mRNA to actin mRNA to control for fluctuations in the recovery of internal mRNA populations not resulting from the vitamin K or warfarin treatment.

Representative slot-blot analyses and tracings of the densitometric scans are illustrated in Fig 3 for actin and factor X mRNA after 24 hour treatment with warfarin, vitamin K, or medium alone. The integrated areas under the curves of the densitometer scan were linear through the concentration range of RNA tested, and for quantitative analysis, the tracings for the middle loadings (1.5 and 3 μg mRNA) were used. No changes were detected in the levels of either actin or factor X mRNA with drug treatment relative to the medium only control. This was the case for all pharmacologic combinations in the study. Since there are no reports of the effects of vitamin K or warfarin on the levels of cytoplasmic actin or its mRNA, the ratio of factor X mRNA to actin mRNA would reveal any changes in the relative abundance of factor X mRNA. Table 1 summarizes the results for ratios of factor X mRNA to actin mRNA in Hep G2 cells subjected to the 3×3 fixed factor analysis of variance. Although some cultures showed a higher apparent ratio, the amount of factor X mRNA remained constant for the various groups and subgroups. These values were used for the analysis of

Fig 3. Examples of slot-blot analyses of actin and factor X mRNA from Hep G2 cells treated for 24 hours with vitamin K or warfarin. Total cellular RNA from Hep G2 cells was isolated, serially diluted, and blotted onto nitrocellulose as described in Methods. The pDH-1 (factor X) or an actin cDNA²² recombinant plasmid was nick-translated and used as the hybridization probe. (Lanes 1 and 4) RNA from Hep G2 cells treated with 10 $\mu\text{g}/\text{mL}$ vitamin K; (lanes 2 and 5) RNA from cells treated with 1 $\mu\text{g}/\text{mL}$ warfarin; (lanes 3 and 6) RNA from cells treated with media only. Below the slot-blots are the densitometric tracings for lanes 1 and 4. The numbers below the scans correspond to the amount of RNA in the blot. The integrated readings quantitate the amount of mRNA within the actin (lanes 1 through 3) or factor X (lanes 4 through 6) RNA blots but not between.

Table 1. Ratios of Factor X mRNA to Actin mRNA in Hep G2 Cells Treated With Vitamin K and Warfarin*

B/A	Vitamin K	Warfarin	Control
Vitamin	0.92	1.27	1.00
Warfarin	1.31	0.94	1.10
Control	1.45	1.13	1.15

*Hep G2 cells were cultured in serum-free medium only (control) or in medium containing 10 µg/mL vitamin K or 1 µg/mL warfarin for 24 hours (A). Subgroups of cells were washed and cultured for an additional 24 hours in vitamin K, warfarin, or control serum-free medium (B). RNA was isolated from each subgroup culture and blotted with radioactive probes made from nick-translated factor X or actin cDNA inserts. Densitometric tracings of the resulting autoradiograms were integrated, and the arbitrary units of integration were used to determine the ratio of factor X mRNA to actin mRNA.

variance for these ratios (Table 2). Table 2 also summarizes the analyses of variance from the individual RNA blots, total RNA, total secreted protein, and cell number. There were no indications of an effect of warfarin or vitamin K on cell number, total RNA, actin mRNA, the ratio of factor X mRNA to actin mRNA, or total secreted protein for any combination of treatment, as all of the F values were <6.94. Thus, the changes in factor X protein secretion observed with warfarin treatment are not the result of modulation of the steady state level of factor X mRNA.

DISCUSSION

Administration of warfarin to patients results in decreased enzymatic activity and antigen levels of factor X and other vitamin K-dependent coagulation proteins.⁴⁻⁹ Changes in the rate of transcription, translation, protein turnover, or protein secretion may account for this observation.¹⁰⁻¹³ We chose to

examine the effect of warfarin treatment on the steady state levels of factor X mRNA as a first approach to addressing this question. The site of action of this drug is principally on the carboxylating enzyme system present in liver hepatocytes.^{2,3} Hep G2 cells secrete most of the vitamin K-dependent proteins and respond to warfarin and vitamin K in a manner indistinguishable from normal hepatocytes.^{12,21} Therefore, we used this cell line as a model to analyze the mechanism of action for the reduced synthesis of this family of proteins.

A factor X cDNA clone was isolated, partially sequenced, and demonstrated to represent the 5' end of the coding sequence with a nucleotide sequence corresponding to amino acid residues 41 to 56 of the factor X light chain. Our results were identical to those recently reported by another group using nucleotide sequence¹⁹ as well as conventional amino acid sequence analysis.³⁴ This clone was used in northern-blot analyses to identify a single mRNA species of approximately 1700 bases in both the Hep G2 cell line and human liver. Therefore, the mature mRNA in Hep G2 cells and liver appear to be transcribed and processed in the same manner. Since our factor X clone contains nucleotide sequences that encode for both the heavy chain as well as the light chain of factor X, the single mRNA species identified in northern blots further supports the conclusion that human factor X is synthesized as a single chain molecule and subsequently cleaved to the conventionally recognized two-chain form.^{12,18,19}

When the length of mRNA for factor X is compared to sizes of factor X cDNA clones,^{18,19} it appears that about 200 to 250 bases in the mature mRNA may not be translated. The longest reported cDNA clone for factor X is approximately 1440 bp and appears to lack sequences for part of the leader peptide, 5'-untranslated regions and most of the poly (A)⁺ tail.¹⁹ Factor X is expected to have similar leader sequences as other vitamin K-dependent proteins, and although it is difficult to estimate the length of the 5'-untranslated regions, other vitamin K-dependent coagulation factors in bovine and human appear to have a short 5'-untranslated region suggesting that the majority of the untranslated nucleotides in mature factor X mRNA may be in the polyadenylated tail.^{17,19,37-39}

We used factor X and actin recombinant cDNA clones as probes to investigate vitamin K and warfarin treatment on the levels of mRNA in Hep G2 cells. While warfarin specifically reduces secretion of the γ-carboxylated coagulation proteins,^{12,21} the response of these cells to vitamin K is less striking and inconsistent; however, increased levels of prothrombin have been observed.¹² Furthermore, factor X and prothrombin levels respond to vitamin K in cultured rat hepatoma cells.¹⁰⁻¹¹ Measurements of extra- and intracellular levels of factor X and prothrombin indicated that secretion alone could not account for the changes observed in these proteins in response to warfarin or vitamin K.¹⁰⁻¹² Therefore, these drugs may alter the synthetic rates at the transcriptional level of these proteins produced by the hepatoma cells as has been suggested for the in vivo condition.⁴⁰ Among the possibilities for the regulation of mRNA levels might be the stability of the transcripts following drug

treatment.^{41,42} In the present study we found no changes in the levels of total RNA or specific factor X mRNA following incubation of cells with warfarin or vitamin K. Even samples that had duplicate application of the same agent in the experiment showed no alterations in the RNA parameters measured. Thus, it appears that neither warfarin nor vitamin K affect the steady state levels of mRNA in Hep G2 cells. Whether the maintenance of the steady state levels in the drug treated cells is in fact due to an increased rate of transcription of a less stable transcript is unknown; further studies, including measurement of transcript stability, would be necessary to confirm or deny this hypothesis.

Regulation of vitamin K-dependent protein synthesis could occur at the level of translation, intracellular protein turnover, or rate of secretion. Previously, we determined that the changes in the secretion of prothrombin could not be accounted for by increases (warfarin treatment) or decreases (vitamin K addition) in the intracellular concentration of prothrombin.¹² Thus, either changes in the rate of translation or intracellular turnover must be responsible for the protein changes observed in vitro and in vivo in response to these pharmacologic agents. Altered protein conformation due to

covalent modifications, cofactor dissociation, or amino acid substitutions can change the degradation rate.⁴³⁻⁴⁵ The effects of protein carboxylation on turnover rates are not known, but during vitamin K-deficient states the vitamin K-dependent proteins would not be processed normally, and these incompletely modified proteins may be more susceptible to intracellular catabolism. If changes in turnover rates are combined with changes in secretion rates, the effects on extracellular levels of these proteins could be amplified. Changes in both turnover and secretion rates have been suggested to account for intraspecies differences in the amount of descarboxyprothrombin present in the plasma of warfarin treated animals.^{46,47} Since the carboxylase system in Hep G2 cells appears to respond "normally" to vitamin K and warfarin, it should provide a system to analyze the effects of γ -carboxylation on the turnover of this family of homologous coagulation proteins.

ACKNOWLEDGMENT

We wish to thank Carol Papworth for her excellent technical assistance, Lawrence Millstein and Dr Daniel Sulzbach for helpful discussions, and Joy Lozano for preparation of the manuscript.

Protein S Is a Cofactor for Activated Protein C Neutralization of an Inhibitor of Plasminogen Activation Released From Platelets

By Armando D'Angelo, Marion S. Lockhart, Silvana Vigano D'Angelo, and Fletcher B. Taylor, Jr.

Platelets stimulated with thrombin release an inhibitor of plasminogen activator (PAI), which has been shown previously to be neutralized by activated protein C (APC). The requirements for optimal neutralization of PAI activity were investigated. The releasate of gel-filtered human platelets stimulated with thrombin served as a source of PAI. When 6×10^8 platelets/mL were incubated with thrombin (1 IU/mL), the releasate contained 18 to 26 ng/mL PAI as determined by incubation of the releasate with urokinase and measurement of residual urokinase activity on plasminogen (S2251). Preincubation of PAI with up to 4 μ g/mL APC for two hours yielded less than 20% neutralization of PAI activity. In the presence of protein S, phospholipid, and Ca^{2+} , neutralization of PAI activity was

time-dependent with 50% neutralization occurring in two hours with 1 μ g/mL APC. The cofactor effects of protein S and phospholipid were concentration-dependent with half-maximal acceleration at approximately 3 μ g/mL protein S and 10 μ g/mL phospholipid when the experiments were performed at 1 μ g/mL APC. Diisopropylfluorophosphate-inactivated APC, gla-domainless APC, and thrombin-cleaved protein S had no effect on PAI activity, indicating requirement for preservation of the APC active site and of the Ca^{2+} binding ability of both APC and protein S. These results suggest coordinate binding of APC and protein S onto phospholipid membrane as a prerequisite for optimal expression of PAI neutralized by APC.

ACTIVATED PROTEIN C accelerates whole blood clot lysis *in vitro*¹ by multiple mechanisms, many dependent on or accelerated by the presence of mononuclear leukocytes and platelets.² One mechanism by which activated protein C produces this effect is by neutralizing an inhibitor of plasminogen activator released from mononuclear leukocyte-platelet mixtures.³ Activated protein C also neutralizes a plasminogen activator inhibitor found in endothelial cell conditioned media.^{4,5} Immunologic identity of the platelet- and endothelial cell-derived plasminogen activator inhibitors (PAI) had been previously demonstrated.⁶ It was suggested that activated protein C prevented inhibition of tissue plasminogen activator by preventing complex formation with PAI.^{7,8} However, the concentrations of activated protein C required to produce these effects were high relative to the other constituents and to the amount of activated protein C one might expect to be produced under physiologic conditions.

Since protein S is a cofactor for the hydrolysis of factor Va and the anticoagulant activity of activated protein C,⁹ we asked if protein S might also be a cofactor for neutralization of plasminogen activator inhibitor and thus facilitate profibrinolytic activity of activated protein C.

Therefore, we studied the conditions and components necessary for optimum activated protein C neutralization of the PAI released from platelets by thrombin.

MATERIALS AND METHODS

Fibrinolytic Components and Assay

Preparation of fibrinolytic components. Human glu-plasminogen (specific activity of 18 to 20 CU/mg) was purified as described¹⁰ and stored in 20 mmol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.55 at -60°C .

S-2251 (Kabi Diagnostica, Stockholm, Sweden) was stored in 0.5 mol/L NaCl at 3.6 mmol/L concentrations in 1 mL aliquots at -20°C .

High molecular weight human urokinase, (100,000 IU/mg; Calbiochem Corp., La Jolla, Calif) was stored in 50% glycerol, 20

mmol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.55, at -20°C at a concentration of 1000 U/mL.

Human plasmin (15 CU/mg, Kabi Diagnostica, Stockholm, Sweden) was stored in 50% glycerol, 0.001 N HCl, at -20°C at a concentration of 0.5 mg/mL.

Assay and characteristics of fibrinolytic components. Activation of plasminogen to plasmin by urokinase was monitored using S-2251 as substrate.¹¹ This assay was run in three stages to accommodate the requirements of the full-scale experiments in which all components were used. In stage 1, platelet releasate (source of PAI) was incubated for 60 to 240 minutes at 37°C either with Tangen HEPES-0.1% BSA buffer,¹² or with one or more of the following: activated protein C, diisopropylfluorophosphate-inactivated activated protein C, gla-domainless activated protein C, bovine factor Xa, protein S, thrombin-cleaved protein S, phospholipid, CaCl_2 , or EDTA in a final volume of 0.11 mL.

In stage 2, urokinase (10 μ L) was added and incubated for ten minutes at 37°C . For each experiment a calibration curve was constructed with increasing urokinase concentrations (0.5 to 5.0 IU/mL) incubated with 0.11 mL buffer (final volume 0.12 mL). Urokinase activity was stable in buffer for up to six hours at 37°C . In stage 3, 40 μ L of this stage 2 incubate was added to 30 μ L of plasminogen giving a final concentration of 70 μ g/mL of plasminogen. After incubation of this mixture for 15 minutes at 37°C , 30 μ L of S-2251 was added giving a final concentration of 1.0 mmol/L S-2251. The total volume of stage 3 was 0.1 mL. The reaction was stopped by addition of 0.5 mL of 1% acetic acid when the color intensity appeared such that it would have an absorbance of 0.600 (8 to 40 minutes). The extent of hydrolysis of S-2251 by plasmin was

measured by determining absorbance at 405 nm using a Beckman DU7 spectrophotometer.

Under these conditions, kinetic analysis of the rate of S-2251 hydrolysis during stage 3 showed a linear increase of $\Delta A_{405}/\text{min}$ over time for urokinase concentrations in stage 2 ranging from 0.25 to 3 IU/mL, provided sufficient S-2251 was available. This suggested that although plasminogen activation was still taking place during stage 3, this occurred as a linear function of the urokinase concentration present at completion of stage 2. Fig 1 shows a typical concentration-dependent activation of plasminogen by urokinase incubated with either buffer or platelet releasate.

It should be noted that since the reaction of greatest interest involving neutralization of PAI activity in platelet releasate occurred in stage 1 of this assay, the concentration of platelet releasate (% dilution), activated protein C, diisopropylfluorophosphate-inactivated activated protein C, gla-domainless activated protein C, bovine factor Xa, protein S, thrombin-cleaved protein S ($\mu\text{g/mL}$), phospholipid ($\mu\text{g/mL}$), CaCl_2 (mmol/L), and EDTA (mmol/L) are given with respect to stage 1.

Antifibrinolytic Components and Assay

Preparation of platelet releasate. Human platelets (1 to $5 \times 10^9/\text{mL}$), prepared from platelet concentrates within two to four hours of collection in ACD buffer, were incubated with 0.1 mg/mL prostaglandin E_1 at 22°C . After 10 minutes they were gel-filtered through Sepharose 2B equilibrated in Tangen HEPES- 0.1% BSA buffer as described by Carroll et al.¹³

Platelet releasate was prepared from 5 to 7 mL of washed platelets after incubation for 30 minutes at 37°C . The platelets were aggregated by addition of thrombin (1 IU/mL) and centrifuged at $2,000 \times g$ for ten minutes at room temperature. The supernate was harvested and gentamicin (0.25 mg/mL) and (p-amidinophenyl) methanesulfonyl fluoride ($20 \text{ }\mu\text{mol/L}$) were added to inhibit bacterial growth and residual thrombin, respectively.

Fig 1. Inhibition of urokinase activation of plasminogen by PAI in platelet releasate. Stage 1: Tangen HEPES- 0.1% BSA buffer ($\circ$ - $\circ$) or a 50% dilution of platelet releasate in buffer ($\bullet$ - $\bullet$) were incubated for two hours at 37°C (final volume 0.11 mL). Stage 2: Urokinase (0.01 mL) was added to give the final concentrations as shown and incubated for ten minutes at 37°C . Residual urokinase activity on plasminogen was followed in stage 3 as described in Methods. The intercept of the platelet releasate-urokinase concentration dependence curve allows calculations of PAI activity in the platelet releasate. This preparation of platelet releasate (undiluted) contained approximately 20 ng/mL active PAI.

Platelets release protein S upon stimulation with thrombin.^{14,15} According to Schwarz et al¹⁴ between 0.2 and $0.4 \text{ }\mu\text{g}$ protein S is recovered in the supernatant of 3×10^8 platelets stimulated with 1 IU/mL thrombin. To remove protein S from platelet releasate, a mouse monoclonal antibody directed against human protein S (HPS-2, a gift from Dr C.T. Esmon) was used. This was coupled to Affigel 10 (Biorad, Richmond, Calif) at a concentration of 5 mg/mL gel and 0.2 mL of packed beads was incubated with 5 mL of platelet releasate for two hours at room temperature on a rocker. The immobilized antibody was removed by centrifugation. Under the same conditions, up to $50 \text{ }\mu\text{g/mL}$ purified protein S can be completely removed by the immobilized monoclonal antibody as judged by immunoelectrophoresis. Once stored at 4°C , PAI activity remained stable for two to three weeks in the platelet releasate.

Assay and characterization of PAI activity of platelet releasate. A 50% dilution of stock platelet releasate was used in this and all the other studies that follow. This stock contained releasate generated from $1.2 \times 10^9/\text{mL}$ platelet suspensions. Fig 1 shows that the PAI activity of platelet releasate followed a linear pattern in parallel with the urokinase control. Since under these conditions the reaction of PAI with urokinase was complete at all concentrations within the ten-minute incubation period, we concluded that the reaction was stoichiometric as previously suggested.⁶ The intercept of the platelet-releasate-urokinase concentration dependence curve can be used to estimate the amount of active PAI in platelet releasate. In Fig 1, a 50% dilution of platelet releasate neutralized completely the apparent activity of at least 1 IU/mL ($=10 \text{ ng/mL}$) urokinase, giving 100% inhibition (closed circles). Assuming a stoichiometric, essentially irreversible interaction between two proteins of approximate equal molecular weight ($53,000$ v $50,000$), 10 ng/mL urokinase would bind an equal weight/mL of PAI.

As a result, a good approximation of the amount of active PAI in platelet releasate (ng/mL) can be derived from measurement of residual urokinase activity on the calibration curve according to the equation: $[\text{UK}]_{\text{added}} - [\text{UK}]_{\text{residual}} = [\text{Active PAI}]$. In spite of the addition of (p-amidinophenyl) methanesulfonyl fluoride, PAI activity in the platelet releasate declined spontaneously at 37°C (apparent half-life 120 to 180 minutes), consistent with the report of spontaneous decline of PAI activity in endothelial-cell-conditioned media.⁴ Therefore, unless indicated otherwise, PAI activity of platelet releasate is always referred to as the apparent activity observed after a two-hour incubation in stage 1.

Control studies in which plasmin (10 to 100 ng/mL) was added to platelet releasate also were done. No inhibition of plasmin by platelet releasate was observed.

Activated Protein C Components

Human protein C was partially purified from plasma (8 to 10 L) as previously described¹⁵ and separated from contaminating proteins by chromatography on a murine anti-human protein C monoclonal antibody (HPC-4) which requires Ca^{2+} for interaction with protein C.¹⁶ Human activated protein C was prepared from protein C daily by means of insolubilized thrombin-thrombomodulin as described previously.¹⁷ The anticoagulant activity of all preparations of activated protein C was assayed using a factor Xa one-stage assay.¹⁷ The stock solutions of $50 \text{ }\mu\text{g/mL}$ activated protein C in 0.02 mol/L Tris-HCl, 0.1 mol/L NaCl, 4 mmol/L CaCl_2 and 0.1% BSA were stored at 4°C no longer than two days. Working solutions of activated protein C were prepared just before each experiment to the final concentration required in Tangen HEPES- 0.1% BSA buffer, pH 7.4. The gla-domain (residues 1 to 44 of the light chain of protein C) was removed by limited proteolysis with chymotrypsin and chromatography as described by Esmon et al.¹⁸ After activation with thrombin-thrombomodulin¹⁷ the gla-domainless activated protein C

had greater than 90% of the amidolytic activity of a corresponding concentration of activated protein C but less than 10% of its anticoagulant activity. Human protein S was prepared as described by Comp et al.¹⁹ Thrombin cleaved protein S was prepared by incubating protein S (0.5 mg/mL) in 1.5 mL of 20 mmol/L Tris-HCl, 2 mmol/L EDTA buffer, pH 7.4, containing 0.1 mol/L NaCl and bovine thrombin at a final concentration of 50 μ g/mL for 15 minutes at 37 °C. The thrombin then was removed by batch adsorption onto 0.3 mL SP-Sephadex for 30 minutes.

Phospholipid suspensions containing 7.5 mg phosphatidylcholine-phosphatidylserine (70:30 PC:PS) per mL 0.015 mol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.4, were prepared by sonication (Branson model B-3 bath) for 30 minutes at room temperature. These suspensions were stored at room temperature under nitrogen for up to one week.

Other Reagents

The diisopropylfluorophosphate-inactivated activated protein C was prepared by treating activated protein C (0.5 mg/mL) with 10 mmol/L diisopropylfluorophosphate in 0.1 mol/L Tris saline buffer for ten minutes at room temperature. This preparation was dialyzed overnight against 4 L of 20 mmol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.55, and assayed for activated protein C activity using the factor Xa one-stage clotting assay. Less than one percent of the original activity remained.

A stock solution of human α -thrombin prepared as described by Owen et al.²⁰ 610 NIH U/mL, had specific activities from 2,800 to 3,000 IU/mg and was stored in 5 mmol/L MES, 0.15 mol/L NaCl, pH 6.0, at -60 °C.

Activated bovine factor X (Xa) was prepared from purified factor X as described by Skogen et al.²¹ A stock solution of Xa, 0.5 mg/mL, was stored in 2 mmol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.5, at -80 °C. This was a gift from Dr C.T. Esmon.

Bovine serum albumin (BSA) 96% to 99% (fraction V), N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES), gentamicin, phosphatidylcholine, phosphatidylserine, prostaglandin E₁, Sepharose 2B, QAE-Sephadex, and SP-Sephadex were obtained from Sigma Chemical Co (St. Louis, Mo). The (p-amidinophenyl)methanesulfonyl fluoride and diisopropylfluorophosphate were obtained from Calbiochem Corp (La Jolla, Calif). All chemicals were reagent grade.

RESULTS

The concentration-dependent neutralization of PAI activity in platelet releasate by activated protein C is shown in Fig 2. In the presence of EDTA, activated protein C had no PAI neutralizing activity. Addition of Ca²⁺ and low levels of phospholipid did not produce full expression of the PAI neutralizing activity of activated protein C, unless protein S also was present. Requirement for preservation of the active site of activated protein C was demonstrated by failure of diisopropylfluorophosphate-inactivated activated protein C to produce neutralization of platelet PAI (Fig 2). This closely resembled the conditions for the expression of activated protein C anticoagulant activity, suggesting cofactor-dependent binding of activated protein C to phospholipid as an explanation for its increased efficacy. Requirement for preservation of the ability of activated protein C to interact with phospholipid surfaces was demonstrated by substitution of gla-domainless activated protein C for activated protein C. Gla-domainless protein C is normally activated by soluble

Fig 2. Concentration dependence of activated protein C-induced neutralization of PAI activity in platelet releasate. Stage 1: To a 50% dilution of platelet releasate in Tangen HEPES-0.1% BSA buffer final concentrations of activated protein C as shown were added in the presence of either 3 mmol/L EDTA (○-○), 2 mmol/L CaCl₂ and 10 μ g/mL phospholipid (70:30 PC:PS) with (□-□) or without (△-△) 10 μ g/mL protein S (final volume 0.11 mL). Platelet releasate (50% dilution) was also incubated with either buffer (○), bovine Xa (1,2,4 μ g/mL, ▲-▲), gla-domainless activated protein C (1,2,4 μ g/mL) in the presence of 2 mmol/L CaCl₂, 10 μ g/mL protein S, and 10 mg/mL phospholipid (■-■), or activated protein C at the shown concentrations with a 10 molar excess of diisopropylfluorophosphate-inactivated activated protein C in the presence of 10 μ g/mL phospholipid, 2 mmol/L CaCl₂, and 10 μ g/mL protein S (●-●). These mixtures were incubated two hours at 37 °C. Stage 2: Urokinase then was added to give a final stage 2 concentration of 2 IU/mL, and this mixture was incubated an additional ten minutes at 37 °C. In stage 3, residual urokinase activity was measured on a calibration curve obtained with increasing concentrations of urokinase in buffer (0.5 to 5 IU/mL) and relative ng/mL active PAI calculated as described in Methods.

thrombin-thrombomodulin complex, but has no anticoagulant activity due to impaired binding to phospholipid.¹⁸ Gla-domainless activated protein C, in the presence or absence of Ca²⁺, phospholipid, and protein S, produced no neutralization of PAI activity over the same range of concentrations used for activated protein C (Fig 2).

The specificity of activated protein C in neutralizing PAI activity was suggested by substituting bovine Xa, in the presence of phospholipid and Ca²⁺, for activated protein C. Bovine Xa has similar coagulant activity to human Xa in human plasma.¹⁷ Bovine Xa (1 to 4 μ g/mL) had no PAI neutralizing activity.

Figure 3 shows the time-dependence at 37 °C of the neutralization of PAI activity in the platelet releasate by activated protein C. In this experiment, PAI activity declined spontaneously to 50% in four hours. After two hours, PAI activity was specifically reduced to 41% by 1 μ g/mL activated protein C and to 29% by 4 μ g/mL activated protein C in the presence of protein S, phospholipid, and Ca²⁺. By removal of Ca²⁺ from the incubation mixture with 3 mmol/L EDTA, 4 μ g/mL activated protein C produced only 13% neutralization of PAI activity after two hours.

Fig 3. Time course of activated protein C-dependent neutralization of PAI in platelet releasate in the presence of protein S, phospholipid, and Ca^{2+} . Final concentrations of 1 $\mu\text{g/mL}$ activated protein C ($\square$ - $\square$) and 4 $\mu\text{g/mL}$ ($\blacksquare$ - $\blacksquare$) with 10 $\mu\text{g/mL}$ protein S, 10 $\mu\text{g/mL}$ phospholipid (70:30 PC:PS), and 2 mmol/L CaCl_2 or 4 $\mu\text{g/mL}$ activated protein C with the same concentrations of phospholipid and protein S, but with 3 mmol/L EDTA ($\blacktriangle$ - $\blacktriangle$) were added to a 50% dilution of platelet releasate in Tangen HEPES-0.1% BSA in stage 1 at 37 °C. Platelet releasate (50% dilution) was incubated with buffer only, at 37 °C ($\circ$ - $\circ$). At the indicated times urokinase (2 IU/mL) was added and this stage 2 mixture (0.12 mL) incubated for ten minutes at 37 °C. Residual PAI activity (mg/mL) was calculated as described in Methods.

The reconstituted system (activated protein C plus protein S, phospholipid and Ca^{2+}) did not reverse inhibition of urokinase activity by the platelet PAI (Fig 4). Incubation of platelet releasate with urokinase for ten minutes in stage 2, by omitting stage 1, resulted in complete neutralization of 2.5 IU/mL urokinase (line F). Preincubation of platelet releasate with buffer for two hours at 37 °C (stage 1) followed by addition of urokinase produced neutralization of 1 IU/mL urokinase, as a result of spontaneous decline in activity (line D). Activated protein C (4 $\mu\text{g/mL}$) with its cofactors produced virtually complete neutralization of PAI activity after a two hour incubation at 37 °C with platelet releasate in stage 1 (line C). In contrast, incubation of activated protein C with its cofactors, platelet releasate and urokinase for two hours in stage 1 (line E) resulted in a PAI activity which was similar to that of the platelet releasate incubated for ten minutes with urokinase after omission of stage 1 (line F). Urokinase activity was identical upon incubation with buffer for either ten minutes or two hours at 37 °C (lines A and B). These data confirm fast neutralization of urokinase activity by PAI and suggests no significant effect of activated protein C and its cofactors on the equilibrium between urokinase and the PAI.

Neutralization of factor Va by activated protein C is dependent on the concentration of both protein S and phospholipid.²² This appears also to be the case for activated-protein C-dependent neutralization of the platelet PAI. Fig 5 shows the concentration dependence of the cofactor effect of protein S. Increasing concentrations of protein S in the presence of 1 $\mu\text{g/mL}$ activated protein C, phospholipid, and Ca^{2+} reduced PAI activity to 37% with approximate half

Fig 4. Effect of the presence of urokinase on the neutralization of platelet PAI by activated protein C, protein S, phospholipid and Ca^{2+} . The assay was conducted as described in Methods. Stage 1: All samples described below were incubated for 120 minutes at 37 °C; incubation volumes equal to 0.11 mL. A ($\circ$): buffer (Tangen HEPES-0.1% BSA, pH 7.4); B ($\bullet$): urokinase in buffer; C ($\square$): 4 $\mu\text{g/mL}$ activated protein C (66 nmol/L), 10 $\mu\text{g/mL}$ protein S (147 nmol/L), 10 $\mu\text{g/mL}$ phospholipid, and 2 mmol/L CaCl_2 with a 50% dilution of platelet releasate in buffer; D (Δ): platelet releasate (50% dilution) in buffer; E ($\blacksquare$): urokinase, 4 $\mu\text{g/mL}$ activated protein C, 10 $\mu\text{g/mL}$ protein S, 10 $\mu\text{g/mL}$ phospholipid and 2 mmol/L CaCl_2 with a 50% dilution of platelet releasate in buffer; F ($\blacktriangle$): platelet releasate (50% dilution) with urokinase in buffer. Stage 2: Ten-minute incubation at 37 °C; incubation volumes equal to 0.12 mL; addition of 10 μL of either buffer (B, E, F) or urokinase (A, C, D). All urokinase added to give a final concentration in stage 2 as shown on the abscissa. Stage 3 was followed as described in the text. The platelet PAI was spontaneously reduced to about 50% after incubation at 37 °C for 120 minutes (D, F). Incubation of activated protein C with the platelet releasate for 120 minutes followed by addition of urokinase caused virtually complete neutralization of antiactivator activity (C). In the presence of urokinase activated protein C had no effect on the apparent anti-PAI activity (E, F).

maximal acceleration at 3 $\mu\text{g/mL}$. In the absence of activated protein C, 16 $\mu\text{g/mL}$ protein S with phospholipid and Ca^{2+} produced no neutralization of PAI activity. Addition of 21 $\mu\text{g/mL}$ of goat polyclonal anti-human protein S antibody (kindly donated by Dr P.C. Comp) in stage 1, together with activated protein C, phospholipid, Ca^{2+} , and 10 $\mu\text{g/mL}$ protein S, completely abolished PAI neutralization (not shown). Requirement for preservation of the Ca^{2+} binding ability of protein S to support activated protein C-dependent neutralization of PAI was demonstrated by substituting thrombin-cleaved protein S, which binds Ca^{2+} less effectively and which is devoid of any anticoagulant activity,²³ for native protein S. Thrombin-cleaved protein S showed no cofactor activity (Fig 5). Moreover, removal of Ca^{2+} from the incubation mixture with EDTA completely inhibited PAI neutralization by activated protein C in the presence of protein S and phospholipid (not shown).

The concentration dependence of the cofactor effect of phospholipid is shown in Fig 6. Activated protein C (1 mg/mL) was incubated with recalcified platelet releasate and increasing concentrations of phospholipid for two hours

Fig 5. Concentration dependence of protein S on the activated protein C induced neutralization of PAI activity in platelet releasate. Stage 1: To a 50% dilution of platelet releasate in Tangen HEPES-0.1% BSA buffer, final concentration, as shown, of protein S (□-□) or thrombin cleaved protein S (Δ-Δ) were added to 10 μg/mL phospholipid (70:30 PC:PS), 1 μg/mL activated protein C, and 2 mmol/L CaCl_2 . Platelet releasate (50% dilution) was also incubated with buffer. These mixtures (0.11 mL) were incubated two hrs at 37 °C. In stage 2, urokinase was added to give a final stage 2 concentration of 2 IU/mL. Residual active PAI (ng/mL) was calculated as described in Methods. PAI activity was 14 ng/mL in the platelet releasate incubated with buffer (50% dilution) in stage 1. Controls that showed no neutralization of PAI included: protein S plus phospholipid and activated protein C in 3 mmol/L EDTA; protein S plus phospholipid and calcium; protein S alone.

at 37 °C in the presence or in the absence of protein S. Half maximal acceleration of PAI neutralization by activated protein C was observed at approximately 10 μg/mL phospholipid in the presence of protein S as opposed to approximately 30 μg/mL phospholipid in the absence of protein S. At 40 μg/mL and 80 μg/mL phospholipid concentration, protein S cofactor activity was no longer apparent. PAI neutralization was not observed either in the absence of Ca^{2+} or in the absence of activated protein C (with 80 μg/mL phospholipid, Fig 6). If the cofactor effects of protein S and phospholipid are due to interaction of activated protein C with protein S onto the phospholipid surface, one would expect diisopropylfluorophosphate-inactivated activated protein C to behave like a competitive inhibitor of activated protein C. As shown in Fig 2, incubation of a 10 molar excess of diisopropylfluorophosphate-inactivated protein C with increasing concentrations of activated protein C in the presence of its cofactors completely inhibited activated-protein C-dependent neutralization of PAI in platelet releasate.

DISCUSSION

These studies confirm that activated protein C neutralizes the inhibitor of plasminogen activator derived from platelets.³ These studies are the first to demonstrate that protein S is a cofactor for this profibrinolytic effect of activated protein C.

Walker has shown that the rate of factor Va inactivation is

Fig 6. Concentration dependence of phospholipid on the activated protein C induced neutralization of PAI activity in platelet releasate. Stage 1: To a 50% dilution of platelet releasate in Tangen HEPES-0.1% BSA buffer containing 1 μg/mL activated protein C and 2 mmol/L Ca^{2+} , final concentrations of phospholipid (70:30 PC:PS) as shown were added either in the presence (□-□) or in the absence (○-○) of 10 μg/mL protein S. Platelet releasate (50% dilution) was also incubated with buffer (●). These mixtures (0.11 mL) were incubated two hours at 37 °C. In stage 2, urokinase was added to give a final concentration of 2 IU/mL. Residual PAI activity was determined as described in Methods. Controls that showed no significant neutralization of PAI included platelet releasate plus 80 μg/mL phospholipid (Δ), and platelet releasate plus phospholipid (80 μg/mL), 3 mmol/L EDTA, protein S (10 μg/mL), and activated protein C (1 μg/mL) (▽).

increased about eightfold by the addition of protein S to activated protein C.⁹ He also observed that the presence of phospholipid was required for expression of the protein S cofactor activity. He has proposed that protein S increases Ca^{2+} -dependent binding of activated protein C to phospholipid membranes by formation of a 1:1 stoichiometric complex, thus accelerating proteolytic degradation of factor Va on the phospholipid surface.²² Studies on endothelial cell²⁴ and platelet¹⁵ receptors for activated protein C and protein S have confirmed formation of activated protein C-protein S complexes as a prerequisite for factor Va neutralization, although indicating different stoichiometries (1 activated protein C molecule: 20 protein S molecules on platelets; 1:400 on endothelial cells).

Protein S is also required for full expression of the PAI activity of activated protein C. The rate of PAI neutralization is increased at least six- to eight-fold by addition of protein S (Fig 6). Protein S stimulation of PAI inactivation occurred only in the presence of both phospholipid and Ca^{2+} . Both activated protein C and protein S must retain their ability to bind phospholipid vesicles for effective PAI neutralization as shown by the experiments conducted with gla-domainless protein C and with thrombin-cleaved protein S. Therefore, taken together, these data suggest that, as in the case of factor Va neutralization, the qualitative biochemical basis for the cofactor effect of protein S in supporting activated protein C-dependent neutralization of PAI resides in its ability to increase the affinity of activated protein C for phospholipid surfaces. This is consistent with (a) saturability

of both phospholipid and protein S effects (Figs 2 and 6), (b) the finding of no significant protein S cofactor activity in the presence of a large excess of phospholipid (Fig 5), and (c) the inhibitory effect of diisopropylfluorophosphate-inactivated activated protein C on activated protein C (Fig 2).

Accurate quantitative analysis of the concentration dependence of the effects of protein S and phospholipid in our system was hindered by the unavailability of sufficiently high concentration of platelet PAI. Interference by other platelet release products (factor Va, platelet proteases) and/or by residual platelet particles cannot be excluded. Moreover, the estimate of PAI concentration being based on PAI activity does not take into account the possible contribution of inactive forms of PAI. With these limitations, however, we estimate that 44 nmol/L protein S was required for the expression of maximal neutralizing activity of 15.5 nmol/L activated protein C in the presence of 10 μ g/mL phospholipid (Fig 5). When considering that some degree of protein S cleavage commonly occurs during the purification procedures (20% to 30%) and that unknown platelet release products may interfere,²⁵ these figures should be an overestimation of protein S in the stoichiometry of the functional protein S-activated protein C complex on the phospholipid surface.

A major observation is that the concentrations of activated protein C and protein S active in our system are in the physiological range. Approximately 0.10 nmol/L active platelet PAI was specifically neutralized by 15.5 nmol/L activated protein C and 147 nmol/L protein S over a period

of 1 hour (Fig 3). In a whole blood clot lysis system de Fouw et al²⁶ induced half maximal clot lysis in one hour at activated protein C concentrations of 15.5 nmol/L, provided endogenous protein S was present. If their results are due to neutralization of PAI released by physiologic platelet concentrations, this would provide evidence for a physiologic role of the anti-PAI activity of activated protein C. In vivo, sustained generation of activated protein C might thus contribute to the regulation of PAI activity. The clinical consequence of this is that patients with deficiencies of protein C and/or protein S might respond subnormally to a prothrombotic stimulus both during the phase of thrombin formation and fibrin dissolution.

The biochemical mechanism of PAI neutralization by activated protein C remains to be elucidated. Complex formation between the enzyme and the PAI has been reported by Sakata et al,⁵ but not confirmed by van Hinsbergh et al,⁴ who suggested proteolytic cleavage of the PAI as an alternative explanation. Our results confirm that the active site of activated protein C is needed for neutralization of PAI activity and suggest no significant effect of the enzyme plus or minus its cofactors on the equilibrium of the urokinase-PAI complex (Fig 4). Although the similarity observed in the requirements of the PAI neutralizing system and the factor Va neutralizing system are very suggestive of a catalytic action of activated protein C on PAI, only studies with entirely purified components will allow final conclusions.

Characterization of a Monoclonal Antibody Having Selective Reactivity With Normal and Neoplastic Plasma Cells

By Alex W. Tong, Jennifer C. Lee, and Marvin J. Stone

A myeloma cell-reactive monoclonal antibody (MoAb), MM4, was generated from BALB/c mice immunized with alternate injections of cells from two human multiple myeloma (MM) cell lines. Screening by the enzyme-linked immunosorbent assay (ELISA) technique showed that MM4 reacted with human MM cell lines (7 of 7 positive), as well as bone marrow aspirates from MM patients (4 of 4 cases positive). MM4 did not react with marrow aspirates from control patients (3 cases), or with peripheral blood mononuclear (PBM) cells from normal subjects, lymphocytic (12 cases) and myelogenous (8 cases) leukemia patients. In addition, MM4 was negative with polymorphonuclear leukocytes and RBCs from normal donors. By means of the immunoperoxidase technique, the MM4-reactive antigen was detected in paraffin-embedded, Zenker formalin-fixed bone marrow biopsies of MM (12 of 12 cases positive),

Waldenström's macroglobulinemia (2 of 2 cases positive), asymptomatic plasma cell dyscrasia (4 of 4 cases positive), and certain lymphomas (2 of 5 cases positive). Marrow biopsies from lymphocytic (5 cases) and myelogenous (5 cases) leukemias were uniformly negative. The MM4-reactive antigen also was expressed on plasma cells generated from pokeweed mitogen (PWM)-stimulated normal PBM cultures. The pattern of reactivity of MM4 with lymphocytes of B origin was similar to that of the plasma cell MoAb PCA-1. Competitive binding studies showed, however, that these two MoAbs recognized distinct antigenic determinants. These observations suggest that MM4 may be useful for the study of human plasma cell dyscrasias.

MULTIPLE MYELOMA (MM) is a malignant lymphoproliferative disorder of B cells at their terminal stage of differentiation. The etiology of this disorder is poorly understood.¹⁻⁴ The wide spectrum of clinical manifestations of MM is the result of uncontrolled clonal proliferation of the myeloma cell.¹⁻⁷ However, antigenic specificity of the malignant clone is generally difficult to establish.⁴⁻⁶ It is also unclear why certain patients with plasma cell dyscrasias (PCDs) progress to malignant myeloma, whereas others remain in a stable nonprogressive state (benign monoclonal gammopathy).⁶⁻⁸ Since alkylating agents became available for therapy 20 years ago, the prognosis for overt MM has not improved substantially.^{1,2,5-8}

Through hybridoma technology, phenotypic studies of tumor cell types have contributed to a better understanding of certain hematologic malignancies.⁹ Characterization of tumor- or differentiation-antigen expression in leukemias and lymphomas has proven valuable for tumor diagnosis, classification, and prognosis.^{9,10} This approach also has provided the basis for tumor cell-specific targeting in immunotherapy trials.¹¹ By comparison, the immunologic phenotype of the myeloma cell is incompletely understood. The

myeloma cell and its normal counterpart, the plasma cell, lack such common B cell antigens as surface immunoglobulins, Ia, or complement receptors.^{1,10,12} B cell differentiation antigens such as B1, B2, B4, and B5 are also absent.¹⁰⁻¹⁴ Pronounced heterogeneity at the cellular and ultrastructural levels are common in MM.^{2,5}

In an attempt to characterize antigens on the myeloma cell better, we produced a monoclonal antibody (MoAb), MM4, that recognizes a commonly expressed antigen on human MM cell lines. MM4 also reacts with myeloma cells in bone marrow of patients with various forms of PCD, but not with peripheral blood mononuclear (PBM) cells, polymorphonuclear neutrophils (PMN), RBCs, or bone marrow (BM) cells from normal subjects and control patients. The selective reactivity of MM4 makes it potentially useful for the further study of human PCD.

MATERIALS AND METHODS

Cell lines and monoclonal antibodies. The plasma cell lines GM 1312, GM 1500, and GM 1311 were obtained from the NIGMS Human Genetic Mutant Cell Repository, Institute of Medical Research, Camden, NJ. RPMI 8226, ARH-77, HS-Sultan, and the colon carcinoma cell line WiDr were obtained from the American Type Culture Collection, Rockville, MD. LICR/LON was kindly provided by Dr Denis Burger, VA Medical Center, Portland, OR.

The plasma cell-reactive antibody PCA-1 and peripheral blood B cell antibody B1 were obtained from Coulter Diagnostics, Hialeah, FL. OKT3, which identifies peripheral T lymphocytes, and the precursor/activated T cell MoAb OKT10 were obtained from Ortho Diagnostics Systems, Raritan, NJ. MoAbs to the pre-B cell antigen common acute lymphoblastic leukemia antigen (CALLA) and the Ia (HLA-DR-related Ia-like) antigen were purchased from Hybritech, La Jolla, CA. Anti-human immunoglobulin κ and λ light chain antibodies were products of Bethesda Research Laboratory, MD. Antibodies to human immunoglobulin (anti-Ig; heavy and light chain specific) were obtained from Kallestad Laboratories, Austin, TX.

Patient blood and BM specimens. Human PBM cells and BM samples from patients with hematologic malignancies or normal

controls were procured according to the protocol approved by the Institutional Review Board for Human Protection, Baylor University Medical Center (BUMC).

Patients with hematologic malignancies were diagnosed and classified independently by the clinical staff, Department of Oncology, Charles A. Sammons Cancer Center, BUMC. Sections of paraffin-embedded BM biopsies from these patients were obtained from the Department of Pathology, BUMC, after routine histopathological evaluation of the specimens. Immunologic phenotyping studies on leukemic patient PBM cells by immunofluorescence were performed independently by the Diagnostic Immunology Laboratory, BUMC, as described previously.¹⁵

Production of MoAbs. MM4 was generated by an alternate immunization protocol.^{16,17} BALB/c mice were sensitized with four weekly injections of 1×10^7 live cells, alternating with cells from the RPMI 8226 and GM 1312 human MM cell lines. Two booster injections were then given three days apart, alternating with cells from the two cell lines. Somatic hybridization of the sensitized splenocytes with SP2/0-Ag14 myeloma cells (1:1, splenocyte/myeloma cells) was performed 3 days after the last injection, using 50% polyethylene glycol and 5% dimethyl sulfoxide according to the method of Oi and Herzenberg.^{16,18}

Fusion products were cultured in hypoxanthine:aminopterin:thymidine (HAT) and IMDM (Iscoe's modified Dulbecco's medium, GIBCO, Grand Island, NY):15% fetal calf serum (FCS, GIBCO) at 37 °C in 5% CO₂/95% air. One hundred microliters of the cell suspension were dispensed into each well of five 96-well microtiter plates containing syngeneic thymocytes as "filler cells" (10^6 to each well).¹⁶ Supernatant fluids from confluent cultures were screened by ELISA for antibody activity against MM cell lines (RPMI 8226, GM 1312) and PBM cells from normal donors. Hybridomas with desirable reactivity were transferred to 24-well plates, grown to confluence (3 to 5 days) and then cloned twice by limiting dilution. Selected hybrid clones were carried in vivo by injecting 2×10^7 cells intraperitoneally (IP) in Pristane (Aldrich Chemicals, Milwaukee)-primed BALB/c mice.¹⁸

Ascitic fluids were harvested 7 to 10 days after induction. MM4 was partially purified by precipitation with saturated ammonium sulfate solution and adjusted to a concentration of 10 mg/mL.¹⁸

Peripheral blood cell separation. Fractionation of peripheral blood cells was carried out as described previously.¹⁹ RBCs were obtained by dextran (6%; mol wt >250,000) sedimentation (37 °C for 30 minutes) of heparinized whole blood. The leukocyte-rich fraction was resuspended to original volume with RPMI 1640 (GIBCO) and separated into PBM and PMN fractions by centrifugation with Hypaque-Ficoll (Pharmacia Fine Chemicals, Piscataway, NJ).

Enzyme-linked immunosorbent assay. An enzyme-linked immunosorbent assay (ELISA) technique with intact target cells was used for antibody screening, as described previously.¹⁶ Incubation with the primary antibody was carried out at 37 °C for 60 minutes, followed by a peroxidase-conjugated secondary antibody (37 °C for 60 minutes; peroxidase-conjugated goat anti-mouse IgG + IgM, 1:3,000; TAGO, Burlingame, CA) with washings in between. The MoAb reactivity was determined as a function of enzyme reaction to the substrate *o*-phenylenediamine (37 °C for 30 minutes; Sigma, St Louis), measured by absorbance at 492 nm (Titertek Multiskan MC, Flow Laboratories, McLean, VA). Reactions of >0.1 OD U above background were considered positive.

Antibody isotyping. Subclass-specific rabbit anti-mouse immunoglobulins (Mouse Immunoglobulins Subtype Identification Kit, Boehringer Mannheim Biochemicals, Indianapolis) were used in an ELISA assay.¹⁶

Immunoperoxidase staining protocol. Zenker formalin-fixed,

paraffin-embedded BM biopsy sections were deparaffinized overnight, rehydrated, and treated with Lugol's iodine and 5% sodium thiosulfate.²⁰ The sections were washed in distilled water, then treated with 1% H₂O₂ in absolute methanol and normal horse serum. Immunoperoxidase staining involved 60-minute incubations at room temperature with the primary antibody, then secondary antibody (biotinylated horse anti-mouse IgG), followed by the enzyme avidin biotin-conjugated horseradish peroxidase (Vectastain ABC kit; Vector Laboratories, Burlingame, CA) and substrate (0.02% 3-amino-9-ethylcarbazole:0.03% H₂O₂:5% *N,N*-dimethylformamide), as described previously.¹⁶ Sections were counterstained with 0.125% methylene blue. Reactivity in each case was determined by light microscopy, in comparison with a section treated with the negative control MoAb SCLC 1096 that was generated against human small cell lung carcinoma.²¹ According to the frequency of reactive cells, reactivity with MoAb was graded as: -, no difference from background as compared with negative control; +, 5% to 10% of nucleated cells positive; ++, 10% to 20% of nucleated cells positive; and +++, >20% reactive cells.

Colony growth assay. The stem cell colony growth assay for the human myeloma cell line RPMI 8226 was performed as described previously.¹⁶ One hundred microliters of MM4 were incubated with 1×10^5 cells for one hour at room temperature. MoAb-treated cells in duplicate were distributed onto a six-well culture plate (Falcon, Oxnard, CA) in 0.3% agar:IMDM:15% FCS and placed in 37 °C incubator. The number of colonies (with >50 cells) was enumerated under low magnification after 7 days. The percentage of growth inhibition was determined by comparing MM4-treated cultures with those treated with the same concentration of an irrelevant MoAb SCLC 1096.

Proteolysis of RPMI 8226 cells. RPMI 8226 cells were washed twice and resuspended in IMDM at 1×10^7 cells/mL. Thirty-five microliters of pronase (Boehringer Mannheim) at 10 mg/mL were incubated with 700 μ L of cell suspension at room temperature for 1 hour.²¹ The reaction was terminated by washing twice with IMDM:15% FCS at 4 °C.

Biochemical characterization of MM4-reactive antigen. Cells from the RPMI 8226 cell line (2×10^7) were incubated with 0.2 mCi ³⁵S-methionine (New England Nuclear, Boston) in methionine-free media (RPMI 1640 Select-Amine kit, GIBCO) and 5% FCS for four hours.²² The labeled cells were washed twice in RPMI 1640 at 4 °C, resuspended in 2 mL of 0.5% NP40 (Sigma), 0.01 mol/L of Tris-HCl, pH 7.6, containing 1 mmol/L of phenylmethylsulfonyl fluoride (Calbiochem, La Jolla, CA) and 0.02% sodium azide, and kept on ice for 60 minutes. The cell lysate was cleared by centrifugation (10,000 g for 15 minutes), then snap-frozen at -70 °C until use.

Extraction of the ³⁵S-labeled MM4-reactive antigenic determinant was performed using MM4 conjugated to CNBr-activated Sepharose 4B (Pharmacia).²² Cell lysates were passed through the MM4-Sepharose or IgG-Sepharose columns (~50,000 cpm) at a flow rate of 0.1 mL/min. The columns were washed with 10 $\times$ vol of detergent lysate buffer. The antigen-bound gels were removed from the column, suspended in sample buffer (0.001 mol/L of EDTA, 1% sodium dodecyl sulfate, 5% 2-mercaptoethanol) and boiled at 100 °C for four minutes. Ten-microliter samples were introduced onto a 4% to 30% gradient slab gel (PAA 4/30, Pharmacia) side by side with radiolabeled markers of known mol wt (Pharmacia). Electrophoresis was carried out in Tris/acetate buffer (0.04 mol/L of Tris, 0.02 mol/L of CH₃COONa, 0.002 mol/L of EDTA, 0.2% SDS, pH 7.4) for two hours at 125 V, constant current (gel electrophoresis apparatus GE-4, Pharmacia). The gel was developed using Enlightening (New England Nuclear), dried, and then analyzed by autoradiography at -70 °C. The mol wt of the reactive determinant was

calculated by linear regression analysis as a function of its migration distance (Rf) in relationship to radiolabeled known mol wt markers.

Mitogen-stimulated cell cultures. Hypaque-Ficoll-separated PBM cells were suspended in RPMI 1640/10% FCS at 1×10^6 /mL. One milliliter of the cell suspension was incubated with PWM (final dilution 1:50, vol/vol; GIBCO) in 17×100 -mm polystyrene culture tubes (American Scientific Products) for the indicated time period.^{10,12}

Immunoperoxidase reactivity of PWM-stimulated PBM cell cultures was determined using Saccomanno fixative (50% ethanol/2% polyethylene glycol)-treated cells deposited on slides (5×10^5 cells to each slide) by cytospin centrifugation (Shandon Southern, Sewickley, PA).²³ Alternatively, MoAb reactivity was evaluated using the ELISA assay as described above.

Competitive binding assay. A radioimmunoassay was developed to compare MM cell binding by MM4 and PCA-1 (Coulter Immunology, Hialeah, FL). Diethylaminoethanol (DEAE)-chromatography-purified MM4 was labeled with carrier-free ¹²⁵Iodine (New England Nuclear) by the lactoperoxidase method.²⁴ The radiolabeled MoAb was separated from free iodine by being passed over a Dowex column (Dupont Chemicals, Boston),²⁵ dialyzed repeatedly in phosphate-buffered saline (PBS) and adjusted to a final protein concentration of 1 mg/mL according to absorbance at 280 nm. ¹²⁵I-MM4 retained >90% of the reactivity of unlabeled MM4, as determined by ELISA.

Competitive binding with ¹²⁵I-MM4 by unlabeled MM4, PCA-1, or the negative control normal mouse IgG was determined using a microtiter plate containing 5×10^4 attached RPMI 8226 cells to each well (as described in ELISA). Fifty microliters of unlabeled MM4, PCA-1, or normal mouse IgG (Cooper Biomedical, Malvern, PA) at molar ratios from 100:1 to 0.1:1 (unlabeled antibody/¹²⁵I-MM4) were added in triplicate (37 °C for 60 minutes). Target cells then were incubated with ¹²⁵I-MM4 (50 µL per well at 37 °C for 60 minutes) after being washed three times with PBS. ¹²⁵I-MM4 bound to each well was determined in an auto-γ scintillation spectrometer (Packard, Laguna Hills, CA) after the plate was washed five times with PBS. Optimal binding of ¹²⁵I-MM4 (cpm_{max}) was determined with RPMI 8226 cells that were not treated with unlabeled antibody, and compared with binding with unlabeled antibody-pretreated target cells (cpm_{treated}). cpm_{background} was established by determining ¹²⁵I-MM4 binding of normal peripheral blood PBM. The percentage of inhibition of ¹²⁵I-MM4 binding was calculated by the formula:

$$\left(1 - \frac{\text{cpm}_{\text{treated}} - \text{cpm}_{\text{background}}}{\text{cpm}_{\text{max}} - \text{cpm}_{\text{background}}}\right) \times 100\%$$

RESULTS

Production of MoAb MM4. BALB/c mice were sensitized with alternate injections of cells from two MM cell lines, RPMI 8226 and GM 1312. This alternate immunization approach previously has been shown to enhance the generation of tumor-reactive hybridomas in a different human tumor system.¹⁶

More than 90% of wells developed hybrid clones within seven days of fusion. Supernatant fluids from 52% of these wells demonstrated reactivity with at least one of the two immunizing MM cell lines. Initial screening by ELISA showed that 15 wells contained clones reactive with both RPMI 8226 and GM 1312 cells, but not with normal PBM cells. These hybridomas were tested with other MM cell lines

and normal PBM cells. Hybridomas containing the desired reactivity were cloned twice by limiting dilution, then carried in mice peritoneally to generate antibody-rich ascitic fluids.

MoAb screening. To ensure that the MoAb of interest reacted with an antigen commonly expressed in MM, hybridomas were tested with seven different cell lines derived from peripheral blood (RPMI 8226, GM 1312, LICR/LON, ARH-77, and GM 1500), BM (GM1311), or plasmacytoma (HS-Sultan) of MM patients. These cell lines expressed either IgG κ or λ M-components (Table 1), with two of the seven lines (ARH-77, GM 1500) expressing Epstein-Barr virus nuclear antigen (EBNA).^{26,27} The hybrid clone MM4 reacted with all seven MM-derived cell lines tested, as determined by ELISA (Table 1). By comparison, the previously described plasma cell MoAb PCA-1¹² was positive with four of six cell lines tested.

MM4 did not react with PBM cells, RBCs, or PMNs from normal control subjects. The pooled ascitic fluid containing MM4 retained its selective reactivity at a dilution of 1/10,000. Subsequent studies were performed with ascites-derived MM4 that was partially purified by precipitation with a 50% (vol/vol) saturated ammonium sulfate solution.

The MM4-reactive antigen was expressed in BM aspirates from MM patients (4 cases), but was not detected in those from control subjects (normal donor, 1 case; colon carcinoma with no marrow involvement, 1 case). In addition, MM4 was unreactive with chronic myelogenous leukemia (CML) marrow (1 case). The plasma cell MoAb PCA-1 was similarly unreactive with normal PBM (0 of 7 cases positive) and control BM (0 of 2 cases positive), but reacted with BM from CML (1 of 1 case positive) as well as MM patients (4 of 4 cases positive).

Reactivity of MM4 with PBMs from patients with leukemia. Reactivity of MM4 also was examined using PBM cells from patients with lymphocytic or myelogenous leukemia. Their immunological phenotypes were defined by MoAbs to OKT3, OKT10, sIg, B1, Ia, and CALLA. MM4 was uniformly unreactive with PBM cells of chronic or acute myelogenous leukemias (Table 2). The antibody was also negative with T acute lymphocytic leukemia, as well as B leukemias that correspond to B cells at various stages of maturation. The latter included null cell, pre-B, and B acute

leukemias, and B cell chronic lymphocytic leukemia (Table 2). By comparison, PCA-1 was also negative with chronic and acute B cell leukemias, but did react with myelogenous leukemia cells.

Immunoperoxidase reactivity of MM4 with BMs from patients with plasma cell dyscrasias. To delineate further the reactivity of MM4 among PCD, we examined its immunoperoxidase reactivity with Zenker formalin-fixed, paraffin-embedded BM biopsies from patients with MM, Waldenström's macroglobulinemia, or asymptomatic PCD (Table 3). The criteria for the diagnosis of MM were as previously

described.^{6,7} MM4 reacted with 12 of 12 MM BMs, and was equally reactive with marrow biopsies from patients with macroglobulinemia (2 of 2 cases positive) or asymptomatic PCD (4 of 4 cases positive). Reactive plasmacytes showed staining in the plasma membrane and cytoplasm. Nuclear staining was not observed.

To establish the mean frequency of MM4-reactive plasma cells within each PCD patient group, the percentage of MM4-reactive cells was compared with the frequency of plasma cells for each marrow biopsy. Of the 12 cases of MM examined containing 20% to 95% of plasma cells

PC, plasma cells; NT, not tested.

*Immunoperoxidase reactivity was determined by the biotin-avidin complex reaction; the reactivity with each antibody was graded in comparison with that of a negative control antibody. The criteria used were as follows: —, no observable difference from control treated section; +, 5% to 10% of reactive nucleated cells; ++, 10% to 20% of reactive nucleated cells; and +++, >20% reactive nucleated cells.

†Majority plasmacytoid lymphocytes.

(57.9% $\pm$ 25%), 69.4% of plasma cells reacted with MM4, whereas 68.0% reacted with PCA-1. Similarly, 76.8% of the plasma cells in the asymptomatic PCD patient group reacted with MM4 (4 cases, percentage of PC = 16.3 $\pm$ 4.8), and 55.2% reacted with PCA-1. The two macroglobulinemia patients (mean percentage of plasmacytoid lymphocytes, 52.5%) contained 33% MM4-reactive and 22.8% PCA-1-reactive cells.

Immunoperoxidase reactivity of MM4 with BM biopsies from patients with leukemia and lymphoma. As compared with PCD marrow, MM4 reacted poorly with biopsies from leukemia patients. We observed no reactivity with chronic lymphocytic (2 cases) or myelogenous (1 case) leukemias. MM4 also was unreactive with acute lymphoblastic (3 cases) or myelogenous (4 cases) leukemias, whereas PCA-1 reacted with 2 cases from the latter group.

Both MM4 and PCA-1 were tested with bone marrows from patients with nodular (2 cases) and diffuse (3 cases) lymphocytic lymphomas. MM4 reacted with 2 of 3 cases of diffuse lymphocytic lymphomas (poorly differentiated lymphoma, 1 case; undifferentiated non-Burkitt lymphoma, 1 case). The same cases were positive with PCA-1, which, in addition, reacted with 1 of 2 cases of nodular poorly differentiated lymphocytic lymphoma tested. These observations indicate that the MM4-reactive antigen was expressed preferentially in PCDs and certain lymphomas.

MM4 reactivity with PWM-stimulated PBMs. Previous studies have shown that PWM induces differentiation of B cells to plasmacytes *in vitro*.^{10,12,13} To define expression of the MM4-reactive antigen in normal plasma cells, we examined its reactivity with PWM-stimulated normal cell cultures. Two other plasma cell-reactive MoAbs, OKT10 and PCA-1, together with the B cell MoAb B1 and anti-Ig light chain reagents (anti- $\kappa + \lambda$) were used for phenotyping of the cell cultures examined.

PWM cultures at days 0 and 4 expressed B1 (20% to 14%, respectively) and surface immunoglobulins (14% to 8%, respectively), as determined by the immunoperoxidase reaction with cytospin cell preparations (Table 4). These cells were minimally reactive with PCA-1, OKT10, or MM4. B1-positive cells, which included B cells from pre-B to mature presecretory stages of maturation, were significantly decreased at days 7 and 10. By contrast, these cultures from days 7 and 10 contained 10.8% to 22.5%, respectively, of MM4+ cells, and reacted also with PCA-1 (9.5% to 7.2%, respectively) and OKT10 (21.5% to 6.5%, respectively). Anti- $\kappa + \lambda$ reagents reacted with 19.4% to 25.5% of cells from day 7 and day 10 cultures. The reactive cells demonstrated pronounced cytoplasmic staining, as opposed to membrane-positive cells observed in day 0 and day 4 cultures. Morphologically, both MM4+ and PCA-1+ cells resembled plasma cells. Most contained eccentric nuclei and well-developed endoplasmic reticulum.

Competitive binding with ¹²⁵I-MM4. The pattern of reactivity of MM4 appeared to be similar to that of PCA-1, with the exception that MM4 did not react with normal or malignant granulocytes. A competitive binding assay was developed to determine whether these two MoAbs reacted with related antigenic determinants. ¹²⁵I-MM4 binding was

‡Comprised anti-human κ light chain antibody mixed with anti-human λ light chain antibody.

tested with RPMI 8226 cells that were preincubated with unlabeled PCA-1, MM4, or normal mouse IgG. As compared with untreated target cells, preincubation with unlabeled MM4 resulted in 25% to 82% inhibition of ¹²⁵I-MM4 binding, over a molar ratio (unlabeled: labeled MM4) range of 0.1:1 to 100:1 (Fig 1). These observations showed the capability of this assay in detecting antigen-specific competitive binding. Inhibition by MM4 was directly related to concentration of the preincubating antibody (regression analysis, $r = .97$, $F = 98.3$, $P = .000006$). By contrast, preincubation with PCA-1 or normal mouse IgG did not significantly affect ¹²⁵I-MM4 binding (PCA-1: $r = -0.29$, $F = 0.47$, $P = .52$) within the same molar ratio range of 0.1:1 to 50:1. The lack of competitive binding by PCA-1 suggests that MM4 and PCA-1 recognize distinct antigenic determinants.

Immunochemical characterization of MM4 and its antigen. MM4 was of the IgG1, κ isotype, as determined by the

Fig 1. Competitive binding with ¹²⁵I-MM4. ¹²⁵I-MM4 binding with RPMI 8226 cells was determined by a radioimmunoassay after pretreatment of the target cells with MM4 (●), PCA-1 (▲), or normal mouse IgG (■) at the indicated molar ratio concentration (unlabeled antibody: ¹²⁵I-MM4).

ELISA assay using anti-mouse subclass-specific secondary antibodies.

The MM4-reactive antigen was protein in nature, as demonstrated by enzyme digestion studies. Treatment of the RPMI 8226 myeloma cells with pronase resulted in a loss of >95% MM4 reactivity as compared with untreated cells. Similarly, trypsin or chymotrypsin incubation resulted in 63% and 86% loss of reactivity, respectively. The reactive antigen on intrinsically ³⁵S-methionine-labeled RPMI 8226 was extracted by immunoprecipitation and analyzed using SDS-PAGE. Under reducing conditions, MM4 reacted with an antigenic determinant of ~39,000 to 40,000 mol wt (Fig 2).

Effect of MM4 on myeloma cell proliferation in vitro. To investigate the biological effect of MM4 binding, clonogenic stem cell growth of the MM cell line RPMI 8226 was examined after incubation with MM4.

Preincubation with MM4 resulted in a significant decrease in the number of myeloma cell colonies in day 7 cultures (Table 5). Exposure to MM4 at 1.0 mg/mL resulted in 75% to 90% reduction. This effect appeared to be dose-dependent, with a 50% reduction of colony formation after exposure to 0.01 to 0.001 mg/mL of MM4. MM4 did not inhibit colony formation of a nonreactive colon carcinoma cell line WiDr. Similarly, neither cell line was significantly affected by incubation with an irrelevant control MoAb small cell lung carcinoma 1096 (SCLC 1096) over the same antibody concentrations (data not shown), suggesting that inhibition of myeloma stem cell colony formation was directly related to specific binding of MM4.

DISCUSSION

This report describes the immunologic properties of a human myeloma cell-reactive MoAb, MM4, generated by an alternate immunization technique. This approach has been used previously in this laboratory to generate MoAbs to human SCLC tumor antigens.¹⁶ The alternate exposure of BALB/c mice to cells from two different SCLC cell lines promoted reactivity to antigens expressed in both immuniz-

ing cell lines and apparently facilitated MoAb production against commonly expressed SCLC tumor antigens.¹⁶ We used the same rationale to produce MM-reactive MoAbs. To promote humoral immunity toward commonly expressed myeloma-associated antigens that were distinct from immunoglobulin or EBNA determinants, two MM-derived cell lines with different immunological properties were selected for immunization. RPMI 8226 was an IgG, λ light chain-secreting cell line,²⁸ whereas GM 1312 was derived from a IgG, κ myeloma.^{29,30} As is characteristic of myeloma-derived lines, both cell lines were morphologically pleomorphic, comprising cells with lymphoblastoid as well as plasmacytoid features.²⁶⁻³⁰ Most RPMI 8226 cells resembled immature plasma cells by electron microscopy,²⁸ and reacted with the plasma cell antibody PCA-1.¹² By comparison, GM 1312 cells in culture were less well differentiated morphologically, were unreactive with OKT10,³¹ and only weakly reactive with PCA-1. Approximately 38% of GM 1312 cells in culture expressed only cytoplasmic Ig, a feature consistent with plasmacytoid differentiation.³⁰ Unlike RPMI 8226, this cell line expressed EBNA determinants.^{28,30}

Based on reactivity with MM-derived cell lines, it was evident that the MM4-reactive antigen was not related to viral antigen or immunoglobulin light chain components. MM4 reacted with all seven cell lines tested, which comprised both IgG, κ and λ myeloma-derived cell lines that were either EBNA positive or negative. Furthermore, the MM4-antigen was not expressed on normal peripheral blood cells, as shown by negative MM4 reactions with PBM cells, RBCs, or PMN leukocytes.

Among malignancies of B lineage, null cell, pre-B and B acute leukemias, and B cell chronic lymphocytic leukemia corresponded phenotypically to transformed B lymphocytes at different stages of maturation.^{9,10} The demonstrated lack of reactivity with MM4 suggested that this antibody did not recognize the various common B antigens displayed by these cell types, such as receptors to C3, HLA class I or II framework antigens, surface Ig, or previously described B differentiation antigens, including CALLA, B1, B2, B4, and B5.⁹

Immunoperoxidase determinations with BM biopsies confirmed the cell line studies showing that the MM4-reactive

Fig 2. Analysis of MM4-reactive determinants by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Reactive antigens derived from ³⁵S-methionine-labeled cell lysates were extracted by immunoprecipitation with MM4-Sepharose 4B. Lanes A through C, immunoprecipitate with MM4; lanes D and E, immunoprecipitate with normal mouse IgG. Arrow indicates MM4-reactive determinant of 39 to 40 kd.

antigen was commonly expressed on the plasma membrane and in the cytoplasm of myeloma cells. MM4 reacted with BM from MM and other PCDs, including Waldenström's macroglobulinemia and asymptomatic PCD. A lack of MM4 reactivity with PBM cells may reflect an absence of peripheral blood involvement.^{2,3,5,6,32}

Of the limited number of lymphoma cases examined, MM4 reacted only with diffuse lymphocytic lymphomas (two of three cases positive) of undifferentiated non-Burkitt, and poorly differentiated lymphocytic histology. The undifferentiated non-Burkitt tumor represents a pleomorphic small cell lymphoma that is phenotypically similar to transformed lymphoblastoid B cells.³³ Diffuse poorly differentiated lymphocytic lymphomas are related to midstage B cells, but commonly exhibit considerable heterogeneity with respect to cellular differentiation and phenotype.^{5,10} Both MM4-reactive lymphoma cases were also positive with PCA-1 and comprised pleomorphic cell populations with marked variations in cell size and nuclear contours. The MM4-reactive cells in each biopsy were plasmacytoid in appearance. Because of the small number of cases examined, it was unclear if these represented a terminally differentiated subset within the lymphoma cell population or infiltration with normal plasma cells.

Like the differentiation antigens found on early or mature B cells,⁹⁻¹⁴ the few plasma cell antigens described thus far have been detected on both normal and malignant cell types. The MoAb PC-1 described by Anderson and co-workers¹³ reacted with a 28-kd protein in normal and malignant plasma cells. Similarly, several plasma cell-reactive MoAbs described by Gonchoroff and co-workers³⁴ recognized antigens expressed on PCD marrow but not on B-CLL or normal PBM cells. Other MoAb-defined plasma cell antigens include the OKT10-reactive 45-kd glycoprotein found also on normal and activated T cells,³⁵ and the PCA-1 and PCA-2 antigens, which were expressed also on activated T cells, granulocytes, and monocytes, but not on normal B or T cells.¹² Similarly, the MM4-reactive antigen was expressed on plasmacytoid lymphocytes derived from PWM-stimulated cultures. Cells from these short-term cultures reacted poorly with B1 at days 7 and 10 but were positive with MM4 as well as with PCA-1 and OKT10. Thus, the MM4-reactive antigen apparently was expressed on terminally differentiated normal plasma cells as well as their malignant counterparts, although it was absent on unstimulated peripheral blood B lymphocytes. Preliminary studies in our laboratory have shown that MM4 reacts with cells from phytohemagglutinin and concanavalin A-stimulated PBM cultures. Unlike antigens that are PCA-1 or OKT10 reactive, however, the MM4-reactive antigen was not expressed on normal

T cells. The prevalence of plasma cell-associated antigens (as defined by OKT10, PCA-1, and PCA-2) on activated T cells is intriguing. Further experiments will be performed to establish the phenotype of the MM4-reactive cells in T cell mitogen cultures.

Pleomorphism among the monoclonal myeloma cell population is a well-documented phenomenon.^{2,3,5} At the cellular level, heterogeneity can be defined by antigen expression,^{2,10} cell ploidy,^{2,5,6} cell growth kinetics^{3,33} and susceptibility to chemotherapy.^{1,5,8} Although the MM4-reactive antigen was clearly evident in all MM marrows examined, only a portion (69.4%) of the total myeloma cells in each case expressed this antigen. The frequency of MM4-positive cells appeared to be similar among patients with MM and asymptomatic PCD. In contrast, marrow samples from macroglobulinemia patients contained a lower frequency of MM4-reactive cells (33%). This may reflect the smaller number of typical plasma cells in this patient population. The frequency of MM4-positive myeloma cells was similar to that of PCA-1-reactive cells in each patient group. Presently, it is not clear whether these two MoAbs recognize the same subset of myeloma cells. Although the two MoAbs demonstrated a similar pattern of reactivity, competitive binding experiments suggest that they recognize distinct antigenic determinants.

Expression of the MM4-reactive antigen on normal plasma cells, and in apparently equal proportions of MM and asymptomatic PCD cell populations, limits its usefulness as a marker for the diagnosis and classification of PCD. In vitro studies indicated, however, that MM4 binding can inhibit myeloma colony growth in vitro. Karp and colleagues showed that clonogenic colony-forming cells from MM marrow are closely related to kinetically active myeloma cells that proliferate in vivo.³⁶ A plasma cell MoAb such as MM4 that reacts with the stem cell subset thus may be potentially useful in the regulation of myeloma cell growth in vivo or for purging myeloma cells in autologous BM transplantation therapy of MM.³⁷ The efficacy of MM4 in eradicating myeloma cells from BM is currently under investigation in this laboratory.³⁸

ACKNOWLEDGMENT

We express our appreciation to Drs F. Carson and W. Kingsley and the staff of the Department of Surgery and Pathology, Baylor University Medical Center, for assistance in procuring human tissue samples. We also thank Dr Joseph Newman and Donna Nicodemus and the staff of Diagnostic Immunology Laboratory, Baylor University Medical Center, for their help in obtaining blood samples for this study, and Sheryl Koleszar for assistance in the preparation of the manuscript.

In Vitro Regulation of Human Hematopoiesis by Natural Killer Cells: Analysis at a Clonal Level

By F. Herrmann, R.E. Schmidt, J. Ritz, and J.D. Griffin

We studied the effects of a series of well-characterized clones of human natural killer (NK) cells on the proliferation of highly purified normal marrow hematopoietic progenitor cells. Individual NK clones suppressed granulocyte, monocyte, erythroid, or mixed colony formation in a heterogeneous but clonally stable manner. Inhibition of colony growth required a period of close cell contact between NK cell and progenitor cell with maximum inhibition occurring after 8 to 18 hours of preincubation time. The mechanism of killing was at least partially humoral, however, as

cell-free supernatants generated by NK clones "activated" by contact with a target cell also inhibited progenitor cell growth. One of the possible humoral mediators was identified as γ -interferon by studies with specific neutralizing monoclonal antibodies. These results show that clonal NK lines can be further activated by coming in contact with hematopoietic progenitor cells, resulting in substantial inhibition of colony formation in vitro.

© 1987 by Grune & Stratton, Inc.

GROWING EVIDENCE shows that hematopoiesis both in vitro and in vivo can be modulated by certain "accessory" cells, including T cells, monocytes, and marrow stromal cells. Humoral factors released by these cells that either inhibit or promote proliferation of selected subpopulations of hematopoietic progenitor cells have been identified (reviewed in refs 1 and 2). Relatively little is known about direct cell-cell interactions between accessory cells and progenitor cells. In this regard, the possibility that natural killer (NK) cells may be involved in the regulation of hematopoiesis has been suggested both by in vivo studies of murine bone marrow transplantation and in vitro murine and human colony assays.³⁻⁷ The evidence that NK cells may participate in the regulation of human hematopoiesis is indirect. Leukemic proliferations of cells with NK-like activity have been reported in which anemia or neutropenia is a major component of the illness. Several studies have indicated that colony-forming progenitor cells are sensitive to NK-mediated inhibition to a variable extent,⁷⁻¹¹ although in other studies no inhibition has been detected.^{12,13} There have been conflicting reports on the sensitivity of various hematopoietic progenitor cells to NK-cell-mediated lysis, however,⁸⁻¹¹ and stimulation of certain progenitor cells has been reported.^{12,13}

The reasons for the variability of results are uncertain, but

possible contributory factors include heterogeneity of the NK cell population itself,¹⁴ differences in NK cell purification, different states of NK cell activation, and the variable presence of endogenous accessory marrow cells. In an effort to resolve some of the controversies over the effects of NK cells on in vitro human hematopoiesis, we studied the effects of a series of well-characterized clones of human NK cells on the proliferation of highly purified marrow colony-forming cells. These NK clones were selected to represent the various NK cell phenotypes present in normal peripheral blood. The results show that NK clones do not promote hematopoietic colony growth and that individual NK clones suppress subpopulations of progenitor cells in a heterogeneous but clonally stable manner.

Previous studies on the mechanism of NK cell lysis have implicated both direct cell-cell mechanisms and release of a humoral cytotoxic factor, NKCF.¹⁵ We therefore investigated the mechanism of inhibition of CFU-GM by active NK clones. The generation of an inhibitory effect required cell-cell contact, and maximum inhibition was observed only after 8 to 18 hours preincubation time with the target population. The inhibitory activity of NK clones was at least partially mediated by a humoral factor, since similar effects were seen when cell-free supernatants generated by suppressive NK clones activated by contact with progenitor populations were tested. We present evidence that NK-derived colony inhibitory activity (NKCIA) can be separated in part from NKCF, and finally that NKCIA can be partially, but not completely, inhibited by neutralizing monoclonal antibodies to interferon- γ (IFN- γ).

MATERIALS AND METHODS

Source of Human Cells

Normal peripheral blood and normal bone marrow (NBM) were collected into sterile, preservative-free heparin. All normal donors were advised of attendant risks of the procedures and gave informed consent in accordance with Institutional Review Board-approved procedures. The mononuclear cell fraction was separated by Ficoll-Hypaque gradient sedimentation. The BM donors were always unrelated to those individuals from whom NK cell lines were derived (see below). Mycoplasma-free leukemic human cell lines KG1 (myeloblasts), HL60 (promyelocytes), K562 (proerythroblasts) and Epstein-Barr virus (EBV)-transformed B lymphoblastoid cell line Laz 461 and Laz 509 were maintained in RPMI 1640 medium

supplemented with 10% fetal calf serum (FCS), L-glutamine, penicillin-streptomycin, and sodium pyruvate.

Partial Purification of Hematopoietic Progenitor Cells

Hematopoietic progenitor cells were enriched ~100-fold using an immune rosette technique previously described in detail.¹⁶ Monoclonal antibodies used in the purification of blasts included anti-MY8 (pan-myeloid), anti-Mol (clone 904, pan-myeloid), anti-Mo2 (monocyte), anti-B1 and anti-B4 (pan B), anti-T11 and anti-T3 (T), anti-NKH1 (NK) and anti-NKH₂ (NK and basophils), anti-glycophorin A (clone 39, K. Sabbath, J.D. Griffin, unpublished observations, January 1985) and anti-J5 [common acute lymphoblastic leukemia (CALLA) antigen]. Progenitor populations obtained in this way were subjected to a second rosetting step involving selection of HLA-DR-positive cells with I2 monoclonal antibody¹⁷ to improve the enrichment of CFU-GM. In experiments assaying for CFU-E, BFU-E, and CFU-Mix, depletion of glycophorin A-expressing cells was omitted and a second rosetting step was included using monoclonal antibody SC9¹⁸ to enrich for multilineage and erythroid progenitor cells. The 90-kd SC9 antigen is expressed by normal CFU-Mix, BFU-E, CFU-E, and erythroid cells less mature than the orthochromatophilic normoblast. CFU-GM are weakly positive, whereas more mature granulocytic cells are negative.

Generation of Cloned Human Cell Lines

Methods for generation of human NK cloned cell lines have been described in detail.^{14,19,20} In brief, either peripheral blood mononuclear cells (PBMCs) or purified NKH1+ or NKH2+ cells were cloned at one cell per well on a feeder layer of autologous, irradiated (5,000 rad) EBV-transformed B cells. Selected colonies with NK activity were expanded by the addition of culture medium containing lymphocyte-conditioned medium (LCM) (10% to 15% final dilution) every three days. Culture medium was RPMI 1640 supplemented with penicillin-streptomycin, L-glutamine, sodium pyruvate, and 20% human AB serum. All NK cell lines used in these studies have been subcloned at least four times at 100 cells per well on a feeder layer of irradiated PBMCs plus irradiated EBV-transformed B cells. After subcloning procedures, both phenotype and cytotoxic function have remained stable. As control cell lines, two cloned human cytotoxic T cell lines recognizing irrelevant antigens in a major histocompatibility complex (MHC)-restricted manner were kindly supplied by Dr Ellis Reinherz of Dana-Farber Cancer Institute.

Phenotypic Analysis of Cell Surface Antigens and Cytotoxicity of Cloned NK Cells

Phenotypic analysis was performed by indirect immunofluorescence with fluorescein-conjugated goat anti-mouse Ig (Tago, Burlingame, CA) as previously described.^{21,22} Monoclonal antibodies used for phenotype analysis of NK cells included T3, T4, T8, T11, NKH1, and NKH2. Samples were analyzed at 10,000 cells per sample on an Epics C flow cytometer (Coulter Electronics, Hialeah, Fla) using a log amplifier. As negative controls to determine background fluorescence, irrelevant ascites derived from nonreactive hybridomas were used. Monoclonal antibodies were always used at saturating concentrations (1:100 to 1:500). Cytotoxicity of NK clones was assessed using a standard ⁵¹Cr-release assay.¹⁴

Antibodies to IFN- γ and IFN- α

Polyclonal antibody to IFN- α and control antiserum was obtained from the Research Resource Branch, National Institutes of Health,

Bethesda, MD (catalogue nos. G-026-502-568 and G-027-501-568).

A monoclonal antibody (3C11C8), which neutralized recombinant and natural IFN- γ was raised against purified recombinant IFN- γ (the interferon was obtained from Biogen, Cambridge, MA).²³ Ascites fluid from mice bearing 3C11C8 hybridoma cells contained 10⁵ neutralizing U/mL. In all experiments, a second monoclonal antibody (2B4) that binds to IFN- γ but has no neutralizing capacity was used as a control.

Colony Assays

CFU-GM assay. CFU-GM were assayed in Agar (Agar Noble, Difco Laboratories, Detroit) by a modification of the method of Pike and Robinson.²⁴ Underlayers (0.5 mL) were composed of 0.5% agar in Iscove's modified Dulbecco's minimum essential medium (MEM) (IMDM) supplemented with L-glutamine and penicillin-streptomycin and 20% FCS. As a source of colony-stimulating factor (CSF), 10% conditioned medium from the GCT cell line (GIBCO, Grand Island, NY) was added to the underlayer. The overlayer (0.5 mL) was composed of 0.3% agar in the same medium and contained 2.5×10^3 purified myeloid progenitor cells in the presence or absence of 2.5×10^4 cloned NK cells. The NK cells do not proliferate under these culture conditions. The cultures were set up in quadruplicate in 24-well plastic culture plates (Linbro) and were incubated at 37 °C in 5% CO₂ and humidified air. In selected experiments, various anti-IFN- α and IFN- γ (at 1,000 to 3,000 nU/mL) or control antibodies were added to underlayers and overlayers. After 7 and 14 days of culture, overlayers were removed from underlayers by agitation and were dried onto glass slides under filter paper. To determine colony (>40 cells) and cluster (8 to 40 cells) morphology, the dried cultures were fixed in acetone-methanol fixative (60% acetone, 10% methanol, 30 mmol/L of sodium citrate, pH 7.4) for 1 minute, and were then stained for combined naphthol AS-D chloroacetate esterase (CAE) and α -naphthyl acetate esterase (ANAE) to detect granulocyte, granulocyte/monocyte, and monocyte colonies as previously described.²⁵ All slides were counterstained with acid hematoxylin (Sigma, St Louis).

CFU-Mix assay. Mixed granulocyte, erythroid, monocyte, and megakaryocyte colonies were assayed as described.²⁶ Progenitor cells were cultured in triplicate in 1-mL cultures in IMDM containing 0.9% methylcellulose, 30% FCS, 10% preselected conditioned medium from phytohemagglutinin (PHA)-stimulated (day 7 culture) PBMCs (PHA-LCM) free of detectable interferon (assayed by induction of class II HLA antigens on CFU-GM),²⁵ 2×10^{-5} mol/L of 2-mercaptoethanol and 1 U/mL of erythropoietin (Step III, Connaught Laboratories, Swiftwater, Ontario). Progenitor cells were plated at 1×10^3 to 1×10^4 /mL in 35-mm culture Petri dishes (Lux, Newbury Park, CA) in the presence or absence of 10⁵/mL of cloned NK cells. Cell concentrations were chosen so that there were 100 total colonies in each plate to minimize the possibility of colony overlap. In selected experiments antibodies to IFN- γ and IFN- α or control antibodies were added at the time of initiation of cultures which were scored on day 14.

CFU-E, BFU-E assay. Erythroid colonies and bursts were grown in triplicate as described²⁷ in 1-mL cultures of IMDM containing 0.9% methylcellulose, 30% FCS, 0.9% deionized bovine serum albumin (BSA), 2×10^{-4} mol/L of 2-mercaptoethanol, and 2 U/mL of erythropoietin. Erythroid progenitor cells were plated at 5×10^3 /mL in the presence or absence of 5×10^4 /mL cloned NK cells. Well-hemoglobinized colonies on day 7 of culture were scored as CFU-E; late hemoglobinizing bursts were scored as BFU-E at 14 days.

CSF-dependent myeloid progenitor proliferation assay. Proliferation of myeloid progenitors was assayed as described.²⁸ In brief,

1×10^4 /mL of purified myeloid progenitors were cultured in 0.2 mL of RPMI 1640 containing 10% FCS and various concentrations of NK-cell-derived supernatants prepared as described below for 48 hours in round-bottom microtiter 96-well plates (Linbro). In some cultures, GCT-conditioned medium (GIBCO) was added (10% vol/vol) as a source of CSF. Four hours prior to cell harvest, 20 μ L of RPMI 1640 containing 1 μ Ci of ^{3} H-thymidine (TdR) (Schwartz-Mann, Spring Valley, NY) was added. Cells were harvested on an automatic cell harvester (Microbiological Associates), and ^{3} H-TdR incorporation was measured in a Packard scintillation counter (Packard Instruments, Downer's Grove, IL). Assays were performed in triplicate, and results were expressed as mean $\pm$ SD.

Assay for proliferation of cell lines. Proliferation of cell lines KG1 and HL60 was assayed as described for myeloid progenitor cells, except that GCT medium was omitted from the cultures.

Preparation of cloned NK-cell-derived supernatants. Cloned NK cells washed free of their LCM propagation medium were plated either at 6×10^3 cells/well in IMDM containing 20% FCS, 1% GCT medium together with 6×10^2 purified NBM progenitor cells or KG1, HL60, K562, or Laz 509 cells in 96-well V-bottom plates (Linbro) in a total volume of 180 μ L/well, and centrifuged at 200 g for 10 minutes to initiate cell contact. For experiments in which contact was to be minimal, NK cells 2.4×10^4 /well were cultured along with 2.4×10^3 NBM progenitor cells in 24-well flat-bottom plates (Linbro) in a total volume of 0.72 mL/well. In both cases, cell concentration was the same (3.3×10^3 cells/mL). Plates were incubated at 37°C in 5% CO₂. Control cultures were performed under identical conditions in which NBM progenitor cells or KG1, HL60, K562, or Laz 509 cells were omitted. After 18 hours of incubation, cell-free supernatants were collected. In some experiments, aliquots of these supernatants were then cultured for 1 hour at room temperature in the presence or absence of 1,000 nU/mL of monoclonal antibody to IFN- γ (3C11C8) or control antibody.

Assay for colony inhibition by cloned NK cells. To test inhibition of hematopoietic progenitor growth, the different cloned NK populations were cultured at 2.5×10^4 to 10^5 /mL with purified hematopoietic progenitor cells in IMDM-20% FCS, 1% GCT in a NK/progenitor ratio of 10:1 in either of two culture conditions. To maximize cell contact, cells were centrifuged to a pellet (200 g for 10 minutes) in V-bottom microtiter plates and then incubated at 37°C for 4 to 18 hours. To minimize cell contact, cells were cultured in 24-well flat-bottom plates (Linbro) in a final volume of 1 mL. After the desired culture period, cells were transferred together with their culture supernatant into colony assays.

To test NK cell promotion of hematopoietic progenitor growth, cells from different NK clones, washed free of PHA-LCM, were incorporated directly into the various colony assays; exogenous growth supporting factors were not added.

RESULTS

NBM Progenitor Cells

The partial purification of NBM myeloid progenitor populations using a sequential two-step immune rosette technique resulted in preparations of 57% to 73% blasts, 20% to 28% promyelocytes, 1% to 3% more mature myeloid cells, 6% to 9% immature erythroid cells, and <1% lymphocytes and monocytes as previously described.²⁵ Reanalysis of the purified progenitor cells by indirect immunofluorescence using anti-Mo2, anti-B1, anti-T11, and anti-NKH1 revealed <1% fluorescent cells, indicating nearly complete absence of monocytes, B lymphocytes, mature T lymphocytes, and NK cells.

A second rosette step involving the selection of SC9-positive cells resulted in preparations of 28% to 40% blasts, 8% to 12% promyelocytes, 2% to 4% more mature myeloid cells, 49% to 53% immature erythroid cells, and <1% lymphocytes and monocytes.

Characterization of NK Clones

Six NK clones were selected for analysis. The phenotypes and cytotoxic activities of these lines are shown in Table 1, which shows that they were representative of the different types of activated peripheral blood NK cells. Retesting of these lines has shown phenotypic and cytotoxic stability for at least 10 months. Clones CNK8, JT9, and JT10 are T cell-like NK clones with T3/Ti-like structures, whereas clones CNK6, JT3, and JT₁₈ are T3 negative. All clones were shown to be positive for the pan-NK cell antigen NKH1_A, but only CNK6, JT3, and CNK8 reacted with NKH2, which defines a subset of large granular lymphocytes (LGLs) in peripheral blood. Two cytotoxic T3⁺ T cell clones that lack NK activity were included in some experiments as controls.

Regulation of Hematopoietic Colony Growth by Cloned NK Cells

NK clones were tested for colony stimulatory activity by using them as "feeder cells" in colony assays in which standard growth factors were omitted. None of the clones produced humoral factors that promoted the growth of CFU-GM, BFU-E, CFU-E, or CFU-GEMM (data not shown).

Pilot experiments with the CNK8 and JT10 clones revealed that co-culture of these NK cells with BM progenitor cells for 12 hours diminished subsequent CFU-GM colony numbers (Table 2) and that this effect was abrogated by prior irradiation of the NK cells (1,200 rad). Moreover, culture of marrow cells with two cytotoxic T cell clones that lack NK activity did not affect CFU-GM growth (Table 2). A series of experiments were then conducted to determine the culture conditions that resulted in optimum "killing" of CFU-GM, BFU-E, and CFU-GEMM by NK clones. The time of preincubation of NK cells and progenitor cells varied from 4 to 8 hours, the cell ratio varied from 2:1 to 20:1, and the cell contact conditions were either "loose contact" (24-well flat-bottom plate) or "tight contact" (96-well V-bottom plate). As shown in Fig 1, for two representative experiments assaying the effect of clone CNK8 on day 14 CFU-GM, CFU-E, and CFU-GEMM growth, colony inhibition required close cell contact and increased with longer preincubation time. In experiments not shown, the optimal NK/progenitor cell ratio was 10:1.

A series of five NK clones and two non-NK clones were then tested for inhibition of hematopoietic progenitor cells using the "optimum" culture conditions defined above (18 hours of co-culture with close cell contact at a 10:1 ratio) (Table 3). Two cytotoxic but non-NK T cell clones did not inhibit progenitor cell growth under these conditions (data not shown). In contrast, five of five NK clones tested inhibited growth of day 7 CFU-GM by >25% (range 27% to

Table 1. Phenotype and Cytotoxic Activities of Cloned Human NK Cell Lines

NK Clones	Phenotype*						Cytotoxicity†				
	T3	T4	T8	T11	NKH1	NKH2	K562	Laz 461	Laz 509	HL-60	KG-1
CNK6	—	—	—	+	+	+	+++	+	—	++	++
JT3	—	—	—	+	+	+	+++	+	—	+	++
JT ₈ 18	—	—	—	+	+	—	+++	++	—	++	+++
CNK8	+	—	+	+	+	+	+++	++	—	+	++
JT9	+	—	+	+	+	—	+++	+++	—	+	++
JT10	+	—	+	+	+	—	+++	+++	—	+	++

*Cells were considered negative if <10% of the cells and positive if >80% of the cells were reactive with the given monoclonal antibody.

†The cytotoxic activity is expressed as follows: —, <5%; +, 5% to 30%; ++, 30% to 60%; +++, >60%.

67%), whereas all clones inhibited day 14 CFU-GM by >25% (range 25% to 90%) (Table 3). All clones inhibited CFU-E growth by >25% (range 13% to 55%), whereas only three clones inhibited BFU-E by >25%. CFU-Mix were inhibited by >25% by three clones.

Inhibition of different colony types varied among individual clones. For instance, clone JT9, a poor inhibitor of CFU-Mix, strongly suppressed day 14 CFU-GM and CFU-E. It is notable that individual degree of inhibition was not associated with membrane expression of the anti-T3 or anti-NKH2 defined antigens, since clones with differential inhibitory effects were found in each phenotypic group. Moreover, the types of colonies inhibited by individual NK clones were reproducible from experiment to experiment and with marrow from different donors.

Agar CFU-GM cultures were stained in situ for esterase activities to determine if either granulocyte or monocyte colonies were preferentially sensitive to NK-mediated lysis (Table 4). At day 14, no preferential lineage inhibition of CFU-GM colonies was noted. Overall, granulocytic colonies were suppressed by 22% to 90%, monocyte colonies by 16% to 88%, and mixed granulocyte/monocyte colonies 25% to 89%. At day 7, however, the extent of inhibition of monocyte and mixed colonies (2% to 34% and 4% to 35%, respectively) was significantly lower than the inhibition of granulocyte colo-

nies (21% to 79% inhibition) ($P = .01$ and $.02$, respectively, based on two-sided paired t test) (Table 4), suggesting increased sensitivity of late granulocyte-committed CFU-GM to NK inhibition.

Inhibition of Myeloid and Erythroid Colony Growth by Humoral Factors Released by NK Cells

To investigate the mechanism of NK cell-mediated hematopoietic colony inhibition, we investigated the possibility that a soluble factor might be involved. Cell-free supernatants were obtained by incubating one of two selected NK clones with either purified progenitor cells or various cell lines under two different cell contact conditions (tight v loose cell contact). As shown in Table 5, supernatants derived from co-culture of progenitor cells with a clone (CNK8) that broadly inhibited hematopoietic colony growth subsequently suppressed day 14 CFU-GM colony formation by $58\% \pm 3\%$ and CFU-E formation by $41\% \pm 4\%$. Supernatants derived from co-cultures of an NK-clone (CNK6) that previously demonstrated modest inhibitory function with progenitor cells were much less effective in suppression of day 14

Table 2. Inhibitory Effect of Cloned Human NK Cell Lines on CFU-GM Growth

Cloned Cell Line*	CFU-GM/ 10^4 Cells†	Control (%)‡
T cell clones

NK cell clones (irradiated)		
CNK8	784	110
JT10	798	113

*Cloned cells were cultured with partially purified target cells for 12 hours in a V-bottom microtiter plate followed by cell suspension and assay of CFU-GM. The non-NK T cell clones are major histocompatibility complex-restricted allogeneic cytotoxic T cell clones of irrelevant antigenic specificity that lacked any demonstrable NK activity on K562 cells. Irradiation was 1,200 rad.

†Mean of quadruplicate values. SE < $\pm 20\%$ in each case.

‡The media control contained 708 CFU-GM/ 10^4 cells after 7 days.

Fig 1. Influence of incubation time and degree of cell contact on suppression of day 14 CFU-GM, CFU-E, and CFU-Mix growth mediated by natural killer (NK) clone CNK8. Cells of NK clone CNK8 were cultured with partially purified hematopoietic progenitor cells (10:1) plated for various times either in 24-well flat-bottomed plates (CFU-GEMM, solid squares; CFU-E, solid diamonds; day 14 CFU-GM, solid circles) or in 96-well V-bottom plates (CFU-Mix, open squares; CFU-E, open diamonds; day 14 CFU-GM, open circles). Prior to incubation, 96-well plates were centrifuged to allow close cell contact. Flat-bottomed plates were not centrifuged. Mean $\pm$ SD of two separate experiments is shown. Absolute number of colonies/ 10^4 cells formed in triplicate cultures were: day 14 CFU-GM, 444 ± 72 ; CFU-E, 558 ± 56 ; CFU-Mix, 35 ± 2 .

JT9	33 ± 4	10 ± 3	49 ± 3	81 ± 6	80 ± 9

*The mean ± 1 SD of four separate experiments with four different normal bone marrow donors is shown.

†The absolute number of colonies (per 10⁴ cells) in triplicate cultures formed in the absence of cloned NK cells were: day 7 CFU-GM 788 ± 124; day 14 CFU-GM 436 ± 76; CFU-E 626 ± 140; BFU-E 150 ± 42; and CFU-Mix 34 ± 9.

CFU-GM (21% ± 4% inhibition) and CFU-E (13% ± 2% inhibition). Co-cultures of the same clones with sensitive and insensitive tumor lines revealed that supernatants produced by clones in the presence of sensitive tumor cell lines also contained CIA. Again, tight co-culture conditions resulted in more inhibitory effects (Table 5). CIA produced by CNK8 was more effective in colony inhibition following preincubation with hematopoietic progenitor cells than with sensitive tumor targets, suggesting that hematopoietic cells are particularly effective stimulators of this NK cell line.

Activation of NK Cells to Release Inhibiting Factors

The results shown in Table 5 suggested that "activation" of an NK clone by co-culture with a sensitive cell line induced release of inhibiting factors, whereas co-culture with an NK-resistant line was ineffective. The specificity of these inhibitory factors was further investigated by preparing supernatants conditioned by co-culture of CNK8 cells with either marrow progenitor cells, a resistant cell line (HL-60), or a sensitive cell line (KG-1), and then determining the effect of each supernatant on subsequent DNA synthesis (³H-TdR incorporation) of progenitor cells, HL-60, or KG-1 cells (Table 6). Marrow progenitor cells, composed primarily of granulocyte precursors, required the addition of CSF (GCT medium) for DNA synthesis.

Medium conditioned by unstimulated CNK8 cells had no inhibitory activity for progenitor cells, KG-1, or HL60 cells. In contrast, following stimulation with partially purified

marrow progenitor cells (MPCs), supernatants inhibited DNA synthesis of MPCs, KG-1 cells (NK sensitive) and HL60 cells (NK resistant). Following stimulation by KG-1 cells, supernatants inhibited MPCs and KG-1 cells, whereas stimulation by HL60 cells did not generate inhibitory activity. Supernatants generated following incubation with either MPCs or KG-1 cells were subsequently most effective at inhibiting the original target cell.

These results suggest that more than one inhibitory factor is released by activated NK cells. Because IFN-γ is known to be an effective inhibitor of hematopoiesis,^{25,29} experiments were performed in which the presence of IFN-γ in these supernatants was assessed by adding a neutralizing monoclonal antibody to IFN-γ (Table 6). The inhibitory activity of supernatants produced by CNK8 in the presence of myeloid progenitor cells, but not KG-1 cells, was partially neutralized by antibody to IFN-γ. Nonneutralizing antibody to IFN-γ, however, did not alter proliferation of the target cell populations tested (data not shown).

Role of IFN-γ Released by Cloned NK Cells in Inhibition of Hematopoietic Colony Growth

To analyze further the possible participation of IFN-γ apparently released by cloned NK cells on contact with hematopoietic progenitor cells in the inhibition of growth of various colony types, neutralizing antibody to IFN-γ was added to CFU-GM, CFU-E, BFU-E, and CFU-Mix assays at time of initiation of colony cultures.

The addition of 1,000 neutralizing U/mL of anti-IFN-γ partially abrogated the inhibition of day 7 granulocyte colonies mediated by CNK8 and JT9, but had minimal or no effects on other day 7 CFU-GM, day 14 CFU-GM, CFU-E, BFU-E, or CFU-Mix (Fig 2). In other experiments, the concentration of anti-interferon antibody was increased to 3,000 nU/mL without further reversal of the inhibitory effects of CNK8. These results suggest that IFN-γ is released as a consequence of the interaction between some NK cell lines and hematopoietic progenitor cells and that IFN-γ contributes to the cytotoxic effect of these NK cells on late granulocyte progenitor cells in particular. The failure of high concentrations of neutralizing monoclonal antibody to IFN-γ to abrogate completely the inhibitory effects of NK clones suggests, however, that additional factors are involved in the inhibition of hematopoiesis by these clones.

DISCUSSION

We have investigated the role of NK cells and NK-derived soluble factors in regulating hematopoiesis in vitro by assaying the effects of cloned, activated human NK cell lines on the growth and differentiation of NBM colony-forming cells. Previous studies with these NK cell lines showed that they are useful models of activated human NK cells. They display considerable heterogeneity in the types of tumor target cells they recognize,²⁰ and some lines utilize the T cell antigen receptor (T3/ti complex) for target structure recognition, whereas other NK lines do not.³⁰ The results presented here

show that such NK cell lines do not promote formation of any hematopoietic colony type by themselves and do not release detectable soluble growth factors for colony formation. All clonal lines tested could inhibit one or more colony types in a reproducible manner, however. For most lines, colony inhibition was moderate (25% to 75% inhibition) and required a period of close cell contact of 8 to 18 hours for maximum effect. Finally, during this period of cell contact, soluble factors that mediate similar inhibitory effects are released. One, but probably not the only one, of these factors appeared to be IFN- γ .

*Cells (1×10^4) were cultured in .2 mL of RPMI 1640 medium containing 25% (vol/vol) NK supernatants or medium alone for 48 hours prior to a 4-hour pulse with ³H-TdR. In all cases, culture with supernatant from unstimulated CNK8 cells was indistinguishable from culture with medium alone.

†Percentage of change of ³H-TdR incorporation on treatment with nonneutralizing monoclonal antibody to IFN- γ was consistently ± 2%.

Fig 2. Influence of neutralizing monoclonal antibody to interferon- γ (IFN- γ) on inhibition of colony growth mediated by selected cloned natural killer (NK) lines. Panel A, day 7 CFU-E; panel B, day 14 CFU-GM; panel C, CFU-E, BFU-E, and CFU-Mix. Horizontal striped bar, control monoclonal (2B4); diagonal striped bar, 1,000 nU/mL of anti-IFN- γ (3C11C8). Results are presented as mean of triplicate culture from one experiment. A second experiment gave identical results.

human hematopoiesis has produced some conflicting results. By means of different experimental conditions, NK cells have been reported both to support and inhibit growth of the same hematopoietic colonies.⁸⁻¹³ Growth of peripheral blood-derived BFU-E has been reported to be promoted by soluble factors derived from unstimulated NK cells¹² as was growth of marrow CFU-GM in response to lectin-activated NK cells.¹³ Inhibition of marrow CFU-E was shown by Mangan and colleagues⁸ and Degliantoni and co-workers.⁹ Marrow-derived BFU-E were found to be suppressed by peripheral blood Leu 7 antigen-positive cells⁸ but not when NK cells were separated by selection of B73.1 antigen-positive cells.⁹ NK cells enriched by depletion of peripheral blood adherent cells and selection of the low-density fraction after Percoll density separation were strongly inhibitory to late (day 7) CFU-GM but were much less effective in inhibiting early (day 14) CFU-GM.¹³ In contrast, selection of B73.1-positive cells resulted in suppression of early CFU-GM without affecting late CFU-GM.⁹ These results already suggest that different enrichment procedures for NK cells may select for different NK subpopulations resulting in the observation of different functional activities. In addition, because hematopoietic colony-forming cells constitute only a small fraction of BM mononuclear cells (<0.5%), in many previous studies endogenous marrow accessory cells with potential inhibiting or stimulatory effects of their own (T cells, monocytes) far outnumbered the colony-forming cells. Thus, purification of the target populations (ie, marrow progenitor cells) may be a critical point in studying their direct interactions with NK cells *in vitro*. For example, it was recently demonstrated that NK cells may amplify endogenous T cells to become suppressor effector cells.³¹ In addition, residual monocytes could be stimulated by exogenous or endogenous CSF to release prostaglandins³² adversely affecting colony growth³³ and NK cell activity.³⁴ The effective removal of accessory cells and the higher concentration of progenitor cells in our experiments was designed to minimize these problems and allow determination of the direct effects of NK cells on progenitor cells.

We found that NK cell lines inhibited growth of all identifiable colony types, often with very modest degrees of inhibition (25% to 75%). Different clones tended to inhibit the formation of certain colony types preferentially, but not that of others. Although this was reproducible in these experiments, the differences among different colony types were often small, and we do not conclude from these data that activated NK cells specifically inhibit progenitor cells of

one lineage and not another, although that possibility deserves further investigation. Certain clones (CNK8 and JT9) displayed strong inhibitory capacity against most colony types, whereas others (CNK6) were minimally inhibitory in the same culture conditions. The lack of lineage-specificity of clones such as CNK8 suggests that the target "antigens" are not lineage restricted and that a possible candidate would be a proliferation-associated cell surface structure expressed by all hematopoietic progenitor cells. Although the role of NK-active cells in the regulation of hematopoiesis *in vivo* is unknown, these results suggest that certain NK cells can be activated by exposure to normal hematopoietic cells and can then inhibit proliferation of these cells. The results presented here suggest, however, that sensitivity to hematopoietic cells is not a property shared by all NK cells to an equal extent.

Other investigators have shown that supernatants from NK cells contain factors cytotoxic for tumor target cells (NKCFs) and may also contain inhibitors of colony growth.^{9,10} We investigated the role of inhibitory humoral factors in these studies with clonal NK cells by determining the degree of inhibition of various target cells by soluble factors generated by co-culture of NK cells with both sensitive and resistant tumor cell lines or with marrow progenitor cells. Our results confirm previous findings from Degliantoni and co-workers⁹ in that NKCFs released on contact with sensitive inducers exert inhibition of various colony types. More than one type of inhibitory factor was apparently generated, however, since NK cells activated by KG-1 cells secreted factors that were more effective in inhibiting KG-1 cell proliferation than marrow progenitor cell proliferation, whereas NK cells activated by progenitor cells secreted factors that were more effective in inhibiting progenitor cells than KG-1 cells. Purification of these factors would be of great interest but would be hampered by the limited amount of material obtainable from co-cultures with purified progenitor cell populations.

Because IFN- γ is known as a potent inhibitor of hematopoiesis^{25,26} a potent enhancer of NK cell function³⁵ and is known to be released from virus-induced NK cells,³⁶ we assayed for the presence of IFN- γ activity by neutralizing supernatants with specific anti-IFN- γ monoclonal antibody. Supernatants produced following culture of NK cells with hematopoietic progenitor cells but not with sensitive tumor targets contained inhibitory activity that could be partially neutralized by anti-IFN- γ antibody. It is presumed that the NK cells were the source of the IFN- γ rather than cells in the

progenitor cell fraction since IFN- γ was not detected in the absence of added NK cells, and the progenitor cell fraction should contain very few cells known to be capable of secreting IFN- γ (T cells, endogenous NK cells). If the IFN- γ is in fact secreted by the NK cell lines, these results suggest that different target cells may cause either different types of NK cell activation or, more likely, different degrees of NK cell activation. The different amounts of IFN- γ in NKClA and NKCFs could explain some of the diverse effects of these two supernatants. In colony assays, anti-IFN- γ but not anti-IFN- α or control antibody partially neutralized inhibition of late CFU-GM, and to a lesser extent BFU-E and CFU-GEMM, suggesting that other inhibitory mechanisms may be active in the inhibition of early CFU-GM and CFU-E. As shown, these may be of humoral nature, but since inhibitory effects due to cell-free

NKClA were less pronounced than those observed with NK cells, inhibitory activities related to direct cellular interactions may account for additional effects and have been the subject of further investigations (R.E. Schmidt, manuscript in preparation). The relevance of all in vitro NK assays in clinical situations is unknown. In the studies reported here, interpretation is further complicated by the fact that cloned NK cells represent highly activated cell populations that may have functional receptors distinct from resting NK cells. NK cells or activated NK-like cells may play a pathologically significant role in several clinical situations, however, including reconstitution following allogeneic BM transplantation,³⁷ the development of clonal hematopoietic disorders in NK-deficient Chediak-Higashi patients,³⁸ and in the development of anemia³⁹ and granulocytopenia⁴⁰ in patients with expanded NK cell, T- γ , or LGL populations.

Flow Cytometric Analysis of Human Bone Marrow: I. Normal Erythroid Development

By Michael R. Loken, Virendra O. Shah, Karen L. Dattilio, and Curt I. Civin

Flow cytometry was used to identify maturational differences of erythroid lineage cells in normal human bone marrow by combining physical characteristics, the expression of multiple cell surface antigens, and nucleic acid content. Normal low-density bone marrow cells could be divided into four populations, based on forward and right-angle light scattering. Erythroid cells, at different maturational stages, were found in three of these four marrow subpopulations. The sequentially correlated expression of three cell surface markers—HLe-1, transferrin receptor, and glycophorin—allowed us to study erythroid maturation from the colony forming cell to the mature erythrocyte. HLe-1 was expressed on the earliest identifiable erythroid cells and was progressively lost as the cells matured. Transferrin receptor began to be expressed at the BFU-E stage and disappeared at the late reticulocyte stage. Transferrin receptor expression preceded glycophorin expression, the latter beginning on morphologically recognizable erythroid precursors just after the CFU-E stage. In

contrast to both HLe-1 and transferrin receptor, which were progressively lost during the maturational process, once glycophorin had been maximally expressed on the cell surface, it remained at constant quantities to the mature erythrocyte stage. Although developing nucleated erythroid cells at approximately the normoblast stage had light-scattering properties similar to those of lymphoid cells, these two cell types could be resolved by cell surface antigen expression. Normoblasts were glycophorin positive and HLe negative, whereas lymphoid cells expressed HLe and either Leu 4, Leu 11, or Leu 12. Decreases in cellular nucleic acid content, corresponding first to the extrusion of the nucleus and second to the loss of reticulum, characterized the later stages of erythroid development. These characteristics and instrumentation can be used to purify erythroid cells at various developmental stages.

DIFFERENTIATION and maturation of hematopoietic cells is accompanied by changes in physical, biochemical, and antigenic characteristics that are specific for the various lineages. Previous studies of antigenic expression of bone marrow cells have used a single marker at a time, with little emphasis on the quantitative differences in antigen expression.¹⁻⁴ A more precise description of the continuous maturational sequence of cells can be obtained by correlating several parameters simultaneously in a quantitative manner (a technique applied to study lymphoid cells⁵⁻⁷).

In this study, we used three cell surface markers (glycophorin A, HLe-1, and transferrin receptor) in defining the stages of erythroid maturation in normal human marrow. Glycophorin A is expressed in large quantities on mature erythrocytes but is not present on the earliest precursor cells.^{8,9} In contrast, the HLe-1 antigen is lost during maturation.¹⁰ Transferrin receptor is expressed at intermediate stages of erythroid development.¹¹ Using flow cytometry to correlate the expression of these three cell surface markers with physical characteristics and nucleic acid content, we were able to identify erythroid cells at morphologically recognizable stages of maturation.

MATERIALS AND METHODS

Monoclonal antibodies. Phycoerythrin (PE)-conjugated Anti-Leu-4 (CD3), Anti-Leu-11 (CD16), Anti-Leu-12 (CD19), and rat anti-mouse κ , as well as Anti-HLe-1 FITC were obtained from Becton Dickinson Monoclonal Center, Mountain View, CA. Anti-transferrin receptor (Becton Dickinson) was conjugated to PE following the protocol of Oi and colleagues.¹² Both purified and FITC-conjugated antiglycophorin (10F7) were the kind gifts of Dr R. Langlois, Livermore.¹³

Cell preparation and immunofluorescence. Bone marrow aspirates were obtained from normal volunteers. Collection of samples was performed after approval by the institutional Committee on Investigations Involving Human Subjects with an assurance filed with and approved by the Department of Health and Human Services. The low-density leukocytes ($1.077 \mu\text{g}/\text{cm}^3$, Ficoll-Hypaque, Pharmacia, Piscataway, NJ) were washed in RPMI 1640

containing 10% fetal bovine serum (FBS) and aliquoted for immunofluorescent staining. The cells were suspended at a concentration of $10^7/\text{mL}$. In the experiments in which both antibodies were directly conjugated to the fluorochrome, the first antibody (or mixture of antibodies, as in the experiments using PE Anti-Leu 4,11,12) was added using an amount that gave maximal fluorescence. The cells were incubated on ice for 30 minutes. They were then pelleted and washed with buffer (at least five times the staining volume) before the second antibody was added. After 30 minutes on ice the cells were again washed with buffer. For the experiment in which antiglycophorin was paired with anti-HLe-1, a four-step procedure was used. The cells were first labeled with antiglycophorin, as just described. Following the wash step, the cells were reacted with rat anti-mouse κ PE, incubated on ice, and washed. The cells were then exposed to 10% normal mouse serum for 30 minutes to block free binding sites of the second-step antibody. After the cells were washed with buffer, the anti-HLe-1 FITC was added and the cells were processed as before. After all the staining steps were completed the cells were resuspended to $2 \times 10^6/\text{mL}$ in RPMI 1640 containing 10% FBS.

Nucleic acid staining. Cells were labeled for cell surface antigens using directly FITC-conjugated antibodies and were fixed overnight in 1% paraformaldehyde in phosphate-buffered saline (PBS).¹⁴ The cells were pelleted and resuspended in saline containing 0.2% Tween 20 (Sigma, St Louis). After 15 minutes at 37 °C, the

cells were washed once with PBS. An aliquot of cells was further exposed to 50 $\mu\text{g}/\text{mL}$ of ribonuclease A (Sigma) for 30 minutes at 37 °C. Both the untreated and RNase-treated cells were resuspended in 10 $\mu\text{g}/\text{mL}$ of propidium iodide (PI) for 30 minutes. The cells were washed with buffered saline once and were then analyzed immediately on the flow cytometer.

Flow cytometry. Quantitative fluorescence analysis was performed using a five-parameter FACS 440 (Becton Dickinson Immunocytometry Systems). The optical configuration and filter combinations for two-color immunofluorescence using FITC and PE have been previously described.¹⁵ In the experiments comparing FITC and PI staining, the optical filter in the PE channel was replaced by a 620 LP filter. The argon ion laser was operated at 488 nm using 100 mW of power. The laser beam was focused using a 2-inch focal length spherical lens. A minimum of 50,000 events was collected in list mode on a Consort 30 Data Management System. This permitted reanalysis of the data to demonstrate the correlation between two colors of immunofluorescence for population of cells identified by forward and right-angle light scattering. Contours were drawn at increments of five cells in the bivariate plots. The initial contour level for the populations identified as "Blast" by light scattering was 2. For all other contour plots, the initial level was 5.

The data presented in Figs 1 through 7 were all obtained from a single bone marrow sample in a single experiment. Replicate experiments gave similar staining results.

Morphological studies. Viable cells, stained for two colors of immunofluorescence, were sorted based on the gates indicated in the appropriate figures. Duplicate cytocentrifuge slides were prepared for each sorted fraction of cells. These slides were coded and stained with Wright's Solution, and differential counts made for each sample.

Enumeration of hematopoietic progenitors. The stained bone marrow cells were sorted directly into 24-well multiculture plates (Falcon Plastics, Oxnard, CA) containing 0.25 mL of growth medium consisting of 1% methylcellulose in Iscove's Modified Dulbecco's Medium (IMDM) (GIBCO, Grand Island, NY) with 30% FBS and 50 $\mu\text{mol}/\text{L}$ of 2-mercaptoethanol. For erythroid colonies, 1 U of erythropoietin and 1% Mo of conditioned medium¹⁶ were added, whereas for granulocyte-macrophage colonies 5% placental-conditioned media was added (kindly provided by Dr L. Levitt). The cultures were incubated at 37 °C in 5% CO₂. CFU-E colonies were counted on day 8; BFU-E colonies were counted on day 14. CFU-GM colonies were enumerated on day 11. Because the number of cells sorted into each well varied from 500 to 2,000 (depending on the relative enrichment of the progenitors expected), the number of colonies was expressed on the basis of 2,000 cells sorted for each well.

RESULTS

Physical parameters aid in discriminating between cell types. The forward and right-angle light-scattering contour plot of low-density Ficoll-Hypaque-separated normal human marrow (Fig 1) was similar to that obtained from blood in which the erythrocytes had been lysed using NH₄Cl.¹⁵ Windows L and G corresponded to the lymphocyte and granulocyte populations (respectively) observed in the analysis of blood. Blood monocytes were found in window B, which in the marrow was comprised of immature cells of various lineages, giving rise to the term "blast" window.¹⁷⁻¹⁹ Colony-forming cells were found almost exclusively within this region.¹⁷⁻¹⁹ Window R was unique to marrow and contained nonnucleated RBCs.

The cells within these windows were sorted and differen-

Fig 1. Correlation of forward- and right-angle light scattering of low density, viable human bone marrow. Four populations of cells (R, L, B, and G) were sorted for morphological identification (Table 1). These same gates were used for reanalysis of the list mode data to correlate the immunofluorescence with the light-scattering parameters of each cell.

tial counts of Wright's-stained cell preparations were made (Table 1). Mature, nonnucleated erythrocytes and reticulocytes predominated in population R. Less mature nucleated erythroid precursors (normoblasts) were enriched in population L, along with lymphoid cells. The least mature erythroid precursors identifiable by morphology were found in population B, which included immature cells of all other lineages. Window G contained almost exclusively maturing cells of the granulocytic lineage. Because Window G did not contain many erythroid cells, subsequent analysis in this study focused on the cell surface antigen expression of cells that were within windows R, L, and B.

Discrimination of erythroid and lymphoid cells. The mixture of erythroid and lymphoid cells found in windows R and L (Fig 1) could be distinguished based on cell surface antigen expression (Fig 2). Erythroid cells were specifically identified using FITC-conjugated antiglycophorin A.^{8,9} The lymphoid cells were identified as a group by mixing three PE-conjugated antibodies together; anti-Leu-4 (CD-3 on T cells), anti-Leu-12 (CD-19 on B cells), and anti-Leu-11 (CD-16 on NK cells).²⁰⁻²² As shown in Fig 2, 94% of all cells within the "RBC" light-scattering window were glycophorin⁺, whereas 6% were lymphoid, as defined by the expression of Leu 4, Leu 12, or Leu 11. In the "lymph" window, 75% of the cells were lymphoid, whereas 25% were erythroid. This was confirmed by FACS sorting and morphological analysis (data not shown). Because cells that were unreactive with either FITC or PE antibodies (box in Fig 2, lymph) constituted <0.5% of all cells within windows R and L (Fig 1), >99% of the cells that lie within these light-scattering windows were identifiable as either erythroid or lymphoid.

Common leukocyte antigen (HLe-1) is lost during erythroid development. The common leukocyte antigen (T200, identified by anti-HLe-1) was reported to be expressed on all leukocytes, including hematopoietic progenitor cells, but not mature RBCs.¹⁰ The relationship between

Lymph, lymphoid cells; Blast, blasts identified by light scattering; Gran, granulocyte.

*Cells were sorted based on their light-scattering properties as illustrated in Fig 1.

†Three replicate experiments using different bone marrow preparations were completed.

‡The proportion of cells that was classified in the windows expressed as a percentage of all cells.

§Cytocentrifuge slides were prepared from the sorted cell populations. These slides were stained with Wright's stain, and differential counts were made of the cell preparations.

the loss of HLe-1 and the acquisition of glycophorin A by erythroid cells during erythroid maturation offered a potential means to characterize the early stages of erythroid cell development. The bivariate analysis of normal bone marrow cells stained with antiglycophorin-PE and anti-HLe-1-FITC is shown in Fig 3. The correlation between the two antigens for all cells in normal bone marrow is shown in the "ungated" panel (Fig 3); for cells gated in the light-scattering windows identified in Fig 1 corresponding to windows R (RBC), L (lymph), and G (gran), it is shown in the other panels. Glycophorin⁺ erythroid cells were easily distinguished from the HLe-1⁺ lymphocytes in the RBC and lymph gates (Fig 3 as compared with Fig 2). As expected, no glycophorin⁺ cells were identifiable in the gran window.

The rather heterogeneous population identified as blasts by light scattering (Fig 1B) had a more complex relationship between glycophorin and HLe-1 (Fig 4). A population of strongly glycophorin⁺ cells was clearly identifiable (Glyco⁺⁺⁺, Fig 4). These Glyco⁺⁺⁺ cells expressed equivalent amounts of glycophorin as the mature erythrocytes found in the RBC light-scattering window. In addition, a small population of cells had intermediate amounts of glycophorin. These Glyco⁺ cells had higher quantities of cell surface HLe-1 antigen than did most of the Glyco⁺⁺⁺ cells (Fig 4).

The glycophorin⁻ cells could be subdivided into two populations which differed threefold in quantitative HLe-1 expression ("HLe-1⁺⁺⁺" v "HLe-1⁺⁺", Fig 4). The HLe-

1⁺⁺⁺ cells had more right-angle scatter signal than did the Glyco⁺⁺⁺ cells. Therefore, the data were reanalyzed with the blast window divided into upper and lower sections based on the right-angle scatter signals of the cells (dashed line in Fig 1B). The immunofluorescence of cells in the upper portion of window B is shown in the upper panel of Fig 4, whereas the staining of cells that were in the lower portion of window B are shown in the lower panel. The Glyco⁺⁺⁺ cells and the Glyco⁺ cells were predominantly in the lower portion of the blast window (Fig 1B). Very few cells that expressed glycophorin were found in the upper blast window. The remainder of the cells in the lower window were glycophorin⁻ and expressed intermediate quantities of HLe-1 (Glyco⁻, HLe-1⁺⁺, Fig 4). The glycophorin⁻ cells that were brightly labeled with HLe-1 (Glyco⁻, HLe-1⁺⁺⁺) were the predominant cell population in the upper portion in window B.

From these data, the cells exhibiting light-scattering parameters corresponding to window B, Fig 1, (which could not be delineated by the combination of antiglycophorin and antilymphoid markers) could be subclassified into four groups, based on the expression of glycophorin and HLe-1. Three populations were predominantly within the lower window of the blast gate (Glyco⁺⁺⁺, Glyco⁺, and Glyco⁻, HLe-1⁺⁺). The upper blast window contained cells of the fourth population (Glyco⁻, HLe-1⁺⁺⁺).

Transient expression of transferrin receptor. Transferrin receptor has also been reported to be expressed on

Fig 2. Discrimination between erythroid and lymphoid cells. The marrow cells were labeled with antiglycophorin FITC and a mixture of anti-Leu-4 (CD3), anti-Leu-11 (CD16), and anti-Leu-12 (CD19), all conjugated to phycoerythrin. The immunofluorescence of cells that had light scattering properties in windows R and L of Fig 1 are shown in (A) and (B), respectively. These two types of cells could be distinguished by cell surface antigens into two mutually exclusive groups. Less than 0.5% of the cells with light-scattering characteristics of either RBC or lymph were within the box denoted in (B), indicating that very few cells were negative for both of these fluorochromes.

early erythroid cells but is also expressed on other cell lineages.^{11,23-25} The correlations between the expression of transferrin receptor and HLe-1 on normal marrow cells are shown in Fig 5. A population of cells was identifiable which expressed neither the transferrin receptor nor HLe-1. As shown in Fig 5, all these transferrin receptor⁻, HLe-1⁻ cells had light-scattering properties in the RBC window and thus were erythrocytes. The majority of the cells within this light-scatter window, however, were transferrin receptor⁺, but were very dim for HLe-1 expression. A few HLe-1 brightly labeled (lymphoid) cells could be identified within this population. The cells that had light-scattering characteristics within the lymph window fell into two populations based on transferrin receptor and HLe-1 expression. The HLe-1 bright fraction (lymphoid, as shown in Fig 3) did not express transferrin receptor. In contrast, all the other cells in the lymph window expressed low amounts of HLe-1 (predominantly normoblasts, as shown above) and large quantities of the transferrin receptor.

The correlations between transferrin receptor and HLe-1 for cells within the blast window are also shown in Fig 5. The cell populations identified here are very similar to those identified by correlating antiglycophorin with anti-HLe-1 (Fig 4). The cells that expressed higher amounts of HLe-1 than did granulocytes also expressed transferrin receptor. By comparison with those in Fig 4, these latter cells were predominantly glycophorin⁻.

Fig 3. Correlation between glycophorin and HLe-1 expression on normal marrow. The multiple populations identified in the ungated panel could be identified by gating the data based on the light-scattering characteristics shown in Fig 1. The bright glycophorin⁺ cells were in the RBC and lymph (lymphocyte) windows but not in the gran (granulocyte) window. Note that the intensity of HLe-1 expression was different for cells in the lymph and the gran windows.¹⁰

Correlation of expression of transferrin receptor and glycophorin. The same bone marrow population was simultaneously studied with PE-conjugated antitransferrin receptor and FITC-conjugated antiglycophorin (Fig 6). The glycophorin⁺ cells within the RBC window (erythrocytes) were

Fig 4. Correlation between glycophorin and HLe-1 expression of cells within window B, Fig 1. This "blast" light-scattering window was further divided into "upper" and "lower" portions (dashed line, Fig 1). Four populations were evident: (a) Bright glycophorin⁺ cells (Glyco⁺⁺⁺), predominantly in the lower window; (b) dim glycophorin⁺ cells (Glyco⁺), also in the lower fraction; (c) glycophorin⁻, HLe-1-intermediate labeled cells (HLe-1⁺⁺, Glyco⁻) (lower fraction); (d) glycophorin⁻, HLe-1 bright cells (Glyco⁻, HLe-1⁺⁺⁺) (upper fraction).

Fig 5. Correlation between transferrin receptor and HLe-1 expression on normal bone marrow gated by light-scattering characteristics. Transferrin receptor and glycophorin expression were very similar when correlated with HLe-1 (as compared with Fig 3). The cells that expressed neither transferrin receptor nor HLe-1 were within the RBC light-scattering window. A positive correlation existed between transferrin receptor and HLe-1 expression, evident in the "ungated" panel.

sorted into two populations based on transferrin receptor expression (Table 2). Erythrocytes with polychromasia were more plentiful in the population that expressed transferrin receptor. The relative proportion of cells comprising these two populations varied from one sample preparation to another. Because mature erythrocytes lacked transferrin receptor, the contamination of the marrow sample with mature blood cells increased the population that expressed glycophorin but not transferrin receptor. Sorting experiments also showed that all the glycophorin⁺, transferrin receptor⁺ cells in the lymph window were predominantly nucleated erythroid precursors (Table 2). In comparison, the transferrin receptor⁻, glycophorin⁻ cells were almost exclusively lymphocytes.

The complex correlation between transferrin receptor and glycophorin expression on cells in the blast window is also shown in Fig 6. There were cells that expressed high levels of transferrin receptor and glycophorin on their cell surfaces, cells that expressed neither antigen, and a continuum of cells that connected these two populations. The cells in this window were arbitrarily classified into groups as shown by the boxes in Fig 6. Table 3 presents the proportion of the total marrow cells in each of these populations and the morphologies of these subsets. The cells that were most strongly positive for both glycophorin and transferrin receptor (Fig 6, blast region A) were exclusively of the erythroid lineage and were mostly normoblasts. The cells with intermediate amounts of glycophorin and transferrin receptor (Fig 6, blast region B) were identifiable erythroblasts. The cells that had slightly lower quantities of transferrin receptor but no glycophorin (Fig 6, blast region C) also contained mainly erythro-

Fig 6. Correlation between transferrin receptor and glycophorin expression on normal bone marrow. Two populations of glycophorin⁺ cells could be identified in the RBC window based on transferrin receptor expression. These two populations as well as the two mutually exclusive populations identified in the lymph window were sorted for morphological examination (Table 2). The glycophorin and transferrin receptor expression of the cells within the "blast" light-scattering window showed a convex shape. Cells were sorted from each of the five boxes for morphological examination (Table 3), and for the enumeration of progenitor cells (Table 4).

‡Cytocentrifuge slides were prepared from the sorted fractions and differential counts were made of the Wright's-stained slides.

blasts, but in addition included morphologically "undifferentiated" blasts with large distinctive myeloperoxidase-positive red granules. The cells that were negative for both transferrin receptor and glycophorin (Fig 6, blast regions D, E) were mostly blasts, predominantly of the granulocytic and monocytic lineages.

The populations identified in Fig 6 were sorted and tested for their ability to form colonies in vitro (Table 4). Cells that were bright for both transferrin receptor and glycophorin could not form erythroid colonies (Table 4, window A). Cells within the other windows contained erythroid colony-form-

ing cells with different degrees of enrichment. The greatest enrichment for erythroid colonies on a per-cell basis was found in windows B or C depending on the experiment. Between 20% and 30% of the cells sorted could form erythroid colonies. The majority of erythroid colony-forming cells were found in window D, however. These cells had slightly elevated amounts of transferrin receptor but did not express glycophorin. The granulocyte-macrophage colonies were found almost exclusively in windows D and E in two experiments, but were found in windows B through C in a third experiment. Surprisingly, CFU-E were not clearly separated from BFU-E by transferrin receptor and glycophorin expression. These two colony-forming cell types, operationally defined in these experiments by colony morphology at day 8 v day 14 of culture, were therefore relatively heterogeneous in their transferrin receptor and glycophorin levels.

Nucleic acid content of erythroid cells. The last stages of erythroid development are characterized by the loss of the nucleus and subsequent loss of RNA-containing reticulum. These steps were identified by quantifying the nucleic acid content of the cells using propidium iodide (PI), which intercalates with both double-stranded DNA and double-stranded RNA.^{26,27} To use this nucleic acid stain, bone marrow cells were first labeled with fluorescent monoclonal antibodies and were then fixed with paraformaldehyde. After the cell membranes were permeabilized with detergent, the cells were stained for nucleic acid content.

The correlations between PI staining (on a logarithmic scale) and immunofluorescence, identified by either antitransferrin receptor or anti-HLe-1, are shown in Fig 7. Three cell populations were identified by their different intensities of PI staining in Fig 7A, when an irrelevant (goat anti-mouse IgG FITC) antibody was used. The transferrin receptor⁺ cells (Fig 7B), included a strongly PI⁺ population and a population with intermediate intensity of PI staining. This population of cells with intermediate staining of PI expressed low amounts of HLe-1 (Fig 7C). This intermediate amount of PI staining was shown to be a result of double-stranded RNA (rather than DNA) by the loss of staining after these cells were treated with ribonuclease A (Fig 7D). These reticulocytes were distinguished from platelets, which

*Four replicate experiments were completed.

†Normal bone marrow cells stained with antitransferrin receptor and antiglycophorin were sorted based on both light-scattering and immunofluorescence properties. The blast cells, Fig 1, were divided into five fractions based on glycophorin and transferrin receptor expression as shown in the boxes in Fig 6. In experiment I, cells in boxes B and C as well as D and E were combined and assayed together.

‡The proportion of cells classified into the sorting windows are expressed as a percentage of total cells.

§In experiment IV, fraction A was not assayed.

||The progenitor cells were assayed as described in the Materials and Methods section. The number of colonies is expressed per 2,000 cells sorted.

¶In experiment II, the cells were not assayed for CFU-C.

Fig 7. Discrimination of marrow populations based on nucleic acid content. Bone marrow cells were reacted with antitransferrin receptor FITC (B,D), anti-HLe-1 FITC (C), or with an irrelevant antibody (goat anti-mouse FITC, A). These populations were then stained with propidium iodide (PI) as described in the Materials and Methods section. The cells in panel D were also treated with ribonuclease A. The population of cells with intermediate PI staining were brightly reactive with antitransferrin receptor but were unlabeled with anti-HLe-1. This intermediate PI staining was sensitive to ribonuclease, as shown in panel D.

also contain RNA, since the erythroid cells expressed glycophorin whereas the platelets did not (data not shown).

DISCUSSION

The continuous changes in characteristics associated with the development of hematopoietic cells can be demonstrated by quantitative multiparameter analysis. The correlations among three cell surface markers (glycophorin A, transferrin receptor, and HLe-1), physical characteristics, and nucleic acid content defined the erythroid lineage and its developmental stages. A summary of the data presented in this article is shown in Fig 8, in which the relative quantities of particular antigens are correlated with other changes characterizing erythroid maturation. This approach required multiple-parameter analysis and a large, dynamic range of quantitative detection, since the data are spread over four decades of intensity.

Glycophorin expression was confirmed as a feature of the later stages of erythroid development (glycophorin was not expressed on erythroid colony-forming cells; Table 4). Glycophorin appeared at the erythroblast stage and rapidly reached maximum expression by the normoblast stage. Glycophorin expression was especially useful to discriminate the later erythroid cells from lymphoid cells, since cells of both of these lineages have similar light-scattering properties (Fig 2). Once glycophorin was maximally expressed, the amount in each erythroid cell was remarkably constant from cell to cell and did not change during further maturation (Figs 3

Fig 8. Schematic representation summarizing the characteristics of erythroid cells as they mature. The relative quantities of the cell surface antigens are depicted in the upper portion of the diagram. These antigenic characteristics can be correlated with cell size, morphology, nucleic acid content, and erythroid colony-forming ability.

and 6), even though erythroid cell size decreased during maturation.²⁸ This suggested a net increase in glycophorin density on the cell surface.

The expression of transferrin receptors on erythroid cells preceded the expression of glycophorin. (This was indicated in the convex shape of the bivariate correlation between transferrin receptor and glycophorin shown in Fig 6.) Most erythroid colony-forming cells expressed low to intermediate amounts of transferrin receptor. Unexpectedly, we could not separate CFU-E and BFU-E into discrete fractions based on transferrin receptor/glycophorin levels, although CFU-C tended to have lower expression of transferrin receptor than did BFU-E and CFU-E. The observations by us and others that some erythroid colony-forming cells are apparently transferrin receptor⁻ may be accounted for by quantitative, rather than qualitative, differences.^{1,11} Expression of transferrin receptor is nearly maximal before glycophorin is expressed. Once erythroid cells expressed cell surface glycophorin, they were no longer able to form colonies.⁸ Erythroid lineage cells expressed much higher maximal levels of cell surface transferrin receptor than did cells of other lineages (Fig 5). In addition, transferrin receptor persisted to a very late stage of erythroid cell development (reticulocyte). Both these observations may be related to the unique requirement

of erythroid cells for large quantities of iron needed for hemoglobin synthesis. This quantitative difference in transferrin receptor expression, as well as the decrease in HLe-1 (Fig 5), facilitated the identification of early erythroid cells as distinct from other lineages of cells. After the transferrin receptor reached maximal levels on the erythroid cell surface, its expression decreased progressively with further erythroid maturation, with a dramatic loss of antigen at the late reticulocyte stage (as defined by loss of detectable RNA).

There was a parallel decrease in HLe-1 and transferrin receptor levels during erythroid maturation (Fig 5). The loss of HLe-1 during the development of erythroid cells began almost as soon as the cell became committed to the erythroid lineage. The decreased expression of the T200, common leukocyte antigen (HLe-1) and the increased expression of the transferrin receptor were very early events following the commitment of cells to the erythroid lineage.

The physical characteristics of cells identified by light scattering also changed gradually during the development of erythroid cells. Cell size, as detected by forward-angle light scatter, decreased as the erythroid cells matured (Tables 1 and 2). No abrupt change in forward light-scattering occurred when erythroid cells lost their nuclei. After enucleation, right-angle light scatter increased; this may have resulted from the acquisition of biconcave disc morphology. This increase in right-angle light scattering was seen only on viable cells. (After paraformaldehyde fixation, mature erythrocytes and lymphoid cells had indistinguishable light-scattering properties—data not shown.) Although erythroid and lymphoid cells had similar light-scattering characteristics, they were clearly distinguished by their cell surface antigenic markers.

PI staining was used to measure nucleic acid content of erythroid cells. The loss of the nucleus from the transferrin receptor⁺, glycophorin⁺ normoblast was easily identified by the decrease in PI fluorescence. After the loss of the nucleus, the cells still contained RNA and retained the same cell surface phenotype (transferrin receptor⁺, glycophorin⁺, and HLe-1⁻). These operationally defined reticulocytes next lost transferrin receptor, then the remainder of their RNA, to become mature erythrocytes (transferrin receptor⁻, glycophorin⁺, HLe-1⁻).

The discrete population of cells identified as reticulocytes (Fig 7) may be an artifact resulting from the Ficoll-Hypaque preparation of the bone marrow. Others have shown a continuous loss of RNA during reticulocyte maturation, which is accompanied by a change in buoyant density of the cells.³¹ Therefore, one would expect the very earliest reticulocytes to be found in the buoyant fraction of the density gradient, whereas the later reticulocytes would sediment with the mature erythrocytes. This would result in the identification of a discrete population of early reticulocytes.

The correlated expression of multiple cellular characteristics provided a basis for study of the progression of cells through a single lineage from the most immature to the mature cells. It will be interesting to add other markers, which further subdivide the development of the erythroid lineage, to define more precisely the progression and timing of cellular events during erythroid maturation. By identifying an entire lineage of cells, as we have done with the erythroid lineage, it is also possible to eliminate these cells from the study of other lineages. Thus, it is potentially possible to define precisely the maturational sequence of each lineage of cells by taking advantage of the appropriate cell surface, physical, and biochemical properties.

Heterogeneous Distribution of Transferrin Receptors on Parenchymal and Nonparenchymal Liver Cells: Biochemical and Morphological Evidence

By Wolfgang Vogel, Adrian Bomford, Stephen Young, and Roger Williams

To investigate which cells of the liver express the receptor for transferrin, isolated rat liver cells produced by collagenase perfusion were fractionated by repeated differential centrifugation to produce hepatocytes (95% + 1%, mean $\pm$ SD, $n = 4$) and nonparenchymal cells (97% + 1%, $n = 3$). Saturable, high-affinity binding of ^{125}I -transferrin was demonstrated on intact cells at 4 °C, with average receptor numbers $20,900 \pm 3,160$ (mean + SD, $n = 4$) for hepatocytes and $5,500 \pm 1,520$ ($n = 3$) for nonparenchymal cells. Total cellular receptors measured in detergent permeabilized hepatocytes were $42,000 \pm 18,330$ (mean $\pm$ SD, $n = 3$) per cell and $14,760 \pm 7,120$ ($n = 3$) per cell in the nonparenchymal fraction. Immunocytochemical demon-

stration of transferrin using antitransferrin, peroxidase antiperoxidase complex confirmed that both cell types bound transferrin. There was heterogeneity of the staining reaction since there was no detectable staining on 40% of hepatocytes and 60% of nonparenchymal cells. Microdensitometric analysis of the staining product corroborated the biochemical evidence that hepatocytes have, on average, more than three times more transferrin receptors than do nonparenchymal cells. These findings support the concept that the hepatocyte has a central role in the uptake and storage of transferrin iron.

THE LIVER HAS a central role in mammalian iron metabolism, containing one-third of total body iron.¹ This is stored, mainly in the form of ferritin, in the hepatocytes and to a lesser extent in the nonparenchymal cells of the liver,² namely Kupffer and endothelial cells. On the basis of biochemical evidence, it has been suggested that the uptake of iron into this store is mediated through the presence of a specific saturable binding site on the hepatocyte, the receptor for transferrin.³⁻⁵ The histochemical demonstration of transferrin receptors, by use of a monoclonal antibody on both parenchymal and nonparenchymal cells in human liver tissue, supports this finding.⁶ In direct contrast to the above, however, Soda and Tavassoli and Kishimoto^{7,8} recently reported that they could demonstrate neither binding of transferrin-coated minibeads to parenchymal cells in rat liver by electron microscopy nor binding of radiolabeled transferrin at 4 °C. They concluded that only hepatic endothelial cells express transferrin receptors.

This claim has led us to reexamine the question of which cells in the liver express receptors for transferrin. In the present study, we paid particular attention to purification of hepatocytes from nonparenchymal cells in preparations of rat liver cells obtained by collagenase perfusion.⁹ We present biochemical and morphological evidence that both rat hepatocytes and nonparenchymal liver cells express the receptor for transferrin.

MATERIALS AND METHODS

Cell preparations. Liver cells were obtained from male Wistar rats (200 to 250 g) using Berry and Friend's collagenase (type IV, Sigma, Poole, UK) perfusion method⁹ modified as described.⁴ After filtering through a nylon mesh, the total cell suspension was immedi-

ately transferred to 4 °C and was kept at this temperature during further processing. Siliconized glassware and prechilled plastic tubes were used. The total cell yield was between 650 and 720×10^6 cells per liver, and the viability was 98%, as judged by trypan blue exclusion. To prepare nonenzymatically separated hepatocytes, open fine-needle aspiration biopsies of livers¹⁰ in ether-anesthetized rats were performed. Approximately 10^5 hepatocytes were obtained from a biopsy and washed three times in Hanks' buffered salt-solution (HBSS) containing 1% (wt/vol) bovine serum albumin (BSA) at 37 °C. The cells were then spun onto slides and processed as described later for cells obtained by collagenase perfusion.

The total cell suspension from a collagenase-perfused liver was centrifuged at 50 g for 2 minutes in ice-cold HBSS containing 1% (wt/vol) BSA, and the supernatants were pooled.¹¹ The pellets were resuspended in wash buffer. These centrifugations were carried out up to 10 times. The final pellet was kept at 4 °C after resuspension. The collected supernatants were further centrifuged for 2 minutes at 50 g to remove the remaining hepatocytes, and the pellet obtained by centrifuging these at 700 g for 7 minutes was layered onto a discontinuous iso-osmotic Percoll (Pharmacia, Milton Keynes, Bucks, UK) gradient at a concentration of 10×10^6 cells/15 mL of gradient. The gradients were prepared by adding the required volume of phosphate-buffered saline (PBS), (285 mOsm l^{-1} pH 7.4) to give Percoll solutions of densities 1.08, 1.075, 1.065, 1.055, and 1.045 g/mL. After centrifugation at 800 g for 50 minutes at 4 °C in a MSE Mistral Coolspeed using a swing-out rotor, the fractions between 1.055 and 1.075 g/mL¹² were collected and washed three times in wash buffer by spinning at 500 g for 7 minutes.

Assessment of cellular composition. Aliquots (5×10^4 cells) of the well-mixed suspensions of purified cell preparations were spun onto slides after the separation process, using a Shandon Cytospin 2 at 350 rpm for 15 minutes, air-dried, fixed in cold acetone, and stained with hematoxylin. A total of 2,000 cells from high-power fields representing central and peripheral areas of two specimens of each fraction were examined on a Leitz 20 EB microscope fitted with eyepiece graticules. Hepatocytes and nonparenchymal cells could easily be distinguished by their typical size and morphology.¹³ Kupffer cells were identified by staining for their endogenous marker enzyme peroxidase¹⁴ according to Graham and Karnovsky.¹⁵

Proteins. Transferrin was purified from pooled human and pooled rat plasma to which ferrous ammonium sulphate was added to iron-load the transferrin. A modification of the method of Okada and colleagues¹⁶ was used, in which the ammonium sulphate fractions precipitated between 35% and 75% saturation were desalted by extensive dialysis against distilled water and chromatographed at 4 °C on a column (gel bed, 2×60 cm) of diethylaminoethyl

(DEAE)-Sephacrose (Pharmacia), using a linear 50- to 350-mmol/L gradient of Tris/HCl, pH 8. The pink fractions were pooled, concentrated by ultrafiltration, and reappplied to the column using a 50- to 160-mmol/L Tris gradient as before. Fractions with A470/A410 ratios of >1.0 were pooled and rechromatographed to yield fractions of ratios of >1.3 . This procedure gave a single protein peak in the case of human transferrin and two distinct peaks with rat transferrin. These rat isotransferrins, previously characterized as Tf₁ and Tf₂,¹⁶ were present in a ratio of $\sim 2:1$, respectively. The major isotransferrin Tf₁ from three separate preparations of rat transferrin was used in the present study. These isotransferrins have been previously shown to donate iron equally to the liver and other tissues in the rat.¹⁷

The diferric transferrins were radiolabeled with ¹²⁵I (Amersham International, Bucks, UK) using solid-phase lactoperoxidase as previously described,¹⁸ and the iron saturation of the proteins was confirmed after iodination by polyacrylamide gel electrophoresis (PAGE) in 6 mol/L of urea.¹⁸ Specific activities of the labeled proteins ranged from 500 to 900 cpm/ng. To prepare ¹²⁵I-labeled apotransferrin, the labeled diferric species were dialyzed at 4 °C against three changes of 0.1 mol/L of sodium citrate/acetic acid, pH 4.5, followed by exhaustive dialysis against deionized double-distilled water.¹⁸

Binding assays. Binding assays on intact cells were performed by adding cells to HBSS 1% BSA containing ¹²⁵I-labeled transferrin in a final 0.5-mL vol in flat-bottomed polystyrene tubes. The tubes were gassed with 95% O₂/5% CO₂ and incubated with shaking for 90 minutes at 4 °C. Parallel incubations were performed with at least 100-fold excess of unlabeled human transferrin to estimate nonspecific binding. The cells were washed three times in ice-cold PBS by centrifuging at 500 g at 4 °C and were counted in a γ counter.

To determine the binding affinities of ¹²⁵I-labeled diferric human and rat transferrins to the rat transferrin receptor, rat reticulocytes were produced by phenylhydrazine injection¹⁹ and $2 \pm 0.5 \times 10^8$ washed reticulocytes were added to each tube; 0.1 to 20 μ g/mL of ¹²⁵I-labeled transferrin was added, as was unlabeled transferrin when indicated. In some experiments, ¹²⁵I-labeled rat and human apotransferrins were used. The binding buffers contained 100 μ mol/L of desferrioxamine (Ciba Pharmaceuticals, Horsham, Sussex, UK) to maintain the proteins in the iron-free form.¹⁸ Because apotransferrin binds with lower affinity to the transferrin receptor than does the diferric species, a higher concentration of the labeled proteins (1 to 200 μ g/mL) was used in the binding studies to ensure saturation of the receptor.¹⁸

The binding of diferric transferrin to liver cells was performed by incubating $1.8 \pm 1.0 \times 10^6$ nonparenchymal cells, or $2 \pm 0.25 \times 10^6$ parenchymal cells to each tube with 0.1 to 20 μ g/mL of ¹²⁵I-human transferrin. Alternatively, in experiments to evaluate receptor number in a competitive setting, a fixed amount ($\sim 2,500$ cpm) of ¹²⁵I-diferric human transferrin, labeled to high specific activity ($\sim 5,000$ cpm/ng) was added to each tube. An increasing amount of unlabeled human or rat transferrin (up to 0.5 mg/mL) was added, and the incubations were carried out at 4 °C for 90 minutes with shaking. Cells were washed in PBS and counted as before.

Total cellular receptor number (the sum of membrane and intracellular receptors), was determined on detergent-solubilized cell extracts.²⁰ Six to 12×10^6 cells were dissolved in 1.2 mL of PBS containing 0.1% (vol/vol) Triton X-100 (Sigma) and 1 mmol/L of phenylmethylsulfonyl fluoride (Sigma) and centrifuged at 12,000 g for 15 minutes at 4 °C. The supernatant was divided into 0.2-mL aliquots in 1.5-mL microcentrifuge tubes, and 20 μ g of unlabeled human transferrin was added to two of these. After 15 minutes at 22 °C, 0.3 mL of 0.1 mol/L of Tris/citrate pH 5, containing 0.1% (wt/vol) BSA, 0.1% (vol/vol) Triton X-100, and 200 ng of ¹²⁵I-human transferrin (diferric) was added to all tubes. These were

incubated for 30 minutes at 37 °C, and the transferrin-receptor complex was precipitated by the addition of 0.8 mL of polyethylene glycol 6,000 (12% wt/vol) in 0.1 mol/L of Tris/citrate pH 5.0 containing human γ -globulin (0.1% wt/vol) for 30 minutes at 4 °C. The tubes were centrifuged at 12,000 g for 15 minutes at 4 °C, and the supernatant and precipitate were counted in a γ counter.

Immunoperoxidase technique. Cytospin monolayer cell preparations of the mixed postperfusion population and purified preparations of parenchymal and nonparenchymal cells were air-dried, fixed in cold acetone for 20 seconds,²¹ and further processed as described by Faulk and co-workers,²² modified for the indirect immunoperoxidase method at 4 °C. Endogenous peroxidase was blocked by incubation with 1.5% H₂O₂-PBS (vol/vol) for 30 minutes; incubation with transferrin (0.53 mg/mL) was carried out for 30 minutes, followed by two washes in PBS for 15 minutes. To prevent nonspecific background staining, the specimens were then incubated with 20% normal swine serum (Dakopatts, High Wycombe, Bucks, UK) for 10 minutes. Because human transferrin binds to the rat transferrin receptor with higher affinity than does the native protein (described in Results section), we used human transferrin and a specific heat-inactivated (30 minutes at 56 °C) antiserum against human transferrin raised in rabbits²³ at the highest possible dilution. Radial immunodiffusion and immunoelectrophoresis²⁴ indicated that this antiserum was specific for human transferrin and failed to react with rat transferrin. Control incubations were performed with: (a) purified rat transferrin as ligand, (b) with human apotransferrin in PBS containing 100 μ mol/L of desferrioxamine¹⁸ (Ciba) as ligand, (c) without transferrin, and (d) without antibody. Commercially available bridging antibody and peroxidase-antiperoxidase (PAP)-complex were used in recommended dilutions (Dakopatts). The peroxidase reaction was performed with 0.5% (wt/vol) 3'-3'-DAB (Sigma) Tris-HCl pH 7.8 solution for 2 minutes at room temperature. H₂O₂ was added to a final concentration of 0.5% (vol/vol) just before use.

Microdensitometric quantitation. The colored product of the peroxidase reaction on a specimen containing the mixed parenchymal-nonparenchymal cell populations was quantitated with a Vickers M85 scanning and integrating microscope. Absorbance at 430 nm was measured with a $\times 40$ objective, spot size 1 (0.5 m in diameter in the optical plane of the specimen), field size of 25 m for parenchymal cells or 10 m for nonparenchymal cells. Under these conditions, single cells of randomly chosen clusters throughout the specimen were evaluated after the microscope was calibrated as described.^{25,26} The absorption expressed in arbitrary machine units was corrected for the slide-background, which was assessed by scanning a cell-free area of the specimen.

RESULTS

Comparison of binding of human and rat transferrins to the rat transferrin receptor. To distinguish between receptor-bound ligand and endogenous transferrin in the immunocytochemical staining of liver cells, we occupied the cellular receptors with human diferric transferrin and recognized this with a polyclonal anti-human transferrin antiserum that did not react detectably with rat transferrin. For this reason, experiments were performed first to characterize the binding of ¹²⁵I-human transferrin to the rat transferrin receptor and then to compare this with the binding of iodinated rat transferrin. Equilibrium binding experiments were performed at 4 °C using rat reticulocytes and ¹²⁵I-human diferric transferrin and ¹²⁵I-rat diferric transferrin as ligands. As shown in Fig 1, in which the data from a representative experiment have been plotted according to the method of Scatchard,²⁷ human transferrin (K_d 4.7×10^8 l mol⁻¹) bound

Fig 1. Comparison of the binding of human and rat transferrin to rat reticulocytes. Rat reticulocytes were produced by phenylhydrazine injection and incubated (2×10^8 cells/0.5 mL of Hanks' Balanced Salt Solution, 1% bovine serum albumin) with up to 10 $\mu\text{g/mL}$ of ^{125}I -labeled human or rat transferrin for 90 minutes at 4°C in air, 5% CO_2 . Non-specific binding was estimated in the presence of 100-fold excess of unlabeled human or rat transferrin, respectively. Cells were washed three times in phosphate-buffered saline (PBS) at 4°C and counted in a γ counter. The binding data for human transferrin (O) K_d , $4.6 \times 10^8 \text{ l/mol}^{-1}$; and rat transferrin (●) K_d , $1 \times 10^8 \text{ l/mol}^{-1}$ were plotted according to the method of Scatchard.²⁷

to the rat transferrin receptor with an affinity nearly 5 times higher than that of the homologous transferrin (K_d $1 \times 10^8 \text{ l/mol}^{-1}$). Similar numbers of receptors were recognized by the two transferrin species. Three preparations of human transferrin purified from different batches of serum bound with consistently higher affinity (K_d $6.5 \pm 2 \times 10^8 \text{ l/mol}^{-1}$, mean $\pm$ SD) than that of three preparations of rat transferrin (K_d $0.9 \pm 0.4 \times 10^8 \text{ l/mol}^{-1}$). Confirmation of this difference in the affinity of binding was obtained from experiments in which a fixed amount of ^{125}I -human diferric transferrin was added to rat reticulocytes, and unlabeled human or rat transferrin was used to compete for binding. Fifty percent inhibition of binding was achieved by concentrations of $6.9 \pm 2.6 \times 10^{-8} \text{ mol/L}$ and $4.3 \pm 2.8 \times 10^{-7} \text{ mol/L}$ (mean $\pm$ SD, $n = 3$) with human and rat transferrin, respectively.

The differential in binding affinity was not present, however, in the case of the iron-free proteins, since both human (K_d $2.9 \pm 3.3 \times 10^8 \text{ l/mol}^{-1}$; mean $\pm$ SD, $n = 3$) and rat (K_d $2.5 \pm 2.4 \times 10^8 \text{ l/mol}^{-1}$) apotransferrins demonstrated very low affinity for the receptor.

Cell purification. The total yield of hepatocytes obtained by collagenase perfusion was reduced by differential centrifugation to $30\% \pm 6\%$ (mean $\pm$ SD, $n = 3$). Recovery of nonparenchymal cells from the Percoll gradients after three washings varied between 30% and 50% of the cell number applied. The initial cell viability of $>98\%$ was decreased slightly by the separation procedure but remained

at 95%. The purity of the cell suspension used for the receptor assays was $95\% \pm 1\%$ (mean $\pm$ SD, $n = 4$) for hepatocytes and $97\% \pm 1\%$ (mean $\pm$ SD, $n = 3$) for nonparenchymal cells. This latter fraction contained $30\% \pm 3\%$ (mean $\pm$ SD, $n = 3$) mononuclear cells positive for endogenous peroxidase.

Immunocytochemical demonstration of transferrin binding. In all preparations of liver cells, human transferrin had bound to hepatocytes and nonparenchymal cells, as shown by the antibody-mediated PAP staining of both types of cell (Fig 2). The staining product on the hepatocytes (H in Fig 2) and nonparenchymal cells (NP in Fig 2) was granular and distributed over the cells. The staining reaction was regarded as specific since (a) preincubation of the specimen with purified rat transferrin, (b) omission of the human transferrin, or (c) omission of antibody to human transferrin abolished the staining. Furthermore, when human apotransferrin was used as ligand, under conditions to ensure that it remained iron-free,¹⁸ staining was also abolished. Figure 2 shows that there was individual variation in the staining of the hepatocytes since the cells in the lower part of the Fig 2 showed granular staining whereas those in the upper part demonstrated minimal staining. This heterogeneity was further investigated by staining preparations of purified hepatocytes and nonparenchymal cells. As shown in detail in the following section, 60% of hepatocytes (Fig 3a) showed granular staining of variable intensity, with the remaining cells showing diffuse, very weak staining. In nonparenchymal cells, staining was seen on 30% to 40% of the cells, with the remaining cells showing very weak staining (Fig 3b). This heterogeneity of staining of hepatocytes was also seen on cells that had not been exposed to collagenase and that had been produced by fine-needle liver biopsy. Figure 4 shows two views of such a preparation.

Microdensitometry. To provide an objective comparison of the intensity of the color products on nonparenchymal cells

Fig 2. Anti-human transferrin antibody peroxidase-anti-peroxidase (PAP)-stained preparation of mixed rat liver cells (postperfusion). Hepatocytes (H) and nonparenchymal cells (NP) can easily be identified by their different size and shape. Staining reaction varies between neighboring hepatocytes, suggesting differences in transferrin binding. Leitz photomicroscope, $\times 40$ objective, Ilford Pan F, original magnification; current magnification $\times 19$.

Fig 3. Anti-human transferrin antibody peroxidase-anti-peroxidase (PAP)-stained preparations for purified (A) hepatocytes and (B) nonparenchymal cells. Hepatocytes and nonparenchymal cells show individual variation in staining intensity, with a subgroup of both cell types showing minimal staining.

($n = 380$) and hepatocytes ($n = 350$), a preparation of mixed cells was scanned using a microdensitometer. An estimate of the absorbance due to nonspecific staining and light scattering was obtained by evaluating 20 cells of each type on a control slide from which the antitransferrin antibody had been omitted during the processing. As shown in the histogram (Fig 5) 150 nonparenchymal cells and 205 hepatocytes gave absorbance values greater than those obtained from cells on the control slide. In the nonparenchymal cells, values ranged from 5 to 35 machine units, whereas values in the hepatocytes ranged from 15 to 130 machine units. Comparison of the range of absorbance for the two groups using the Mann-Whitney test²⁸ showed that they were significantly different ($P < .001$).

Fig 4. Anti-human transferrin antibody peroxidase-anti-peroxidase (PAP)-stained preparation (two views) of hepatocytes not exposed to collagenase and produced by fine-needle liver biopsy. Heterogeneity of staining intensity of individual cells is seen (original magnification $\times 25$; current magnification $\times 12$).

Binding of ^{125} I-human transferrin to hepatocytes and nonparenchymal cells. Because of the evidence that dimeric human transferrin binds with high affinity to the rat transferrin receptor, this ligand was used in a series of experiments to investigate the binding of transferrin to purified preparations of hepatocytes and nonparenchymal cells. There was saturable binding of ^{125} I-transferrin at 4 °C to cells of both fractions (Fig 6) with saturation occurring at >12.5 nmol/L of transferrin. Scatchard analysis²⁷ of the data (Fig 7) showed that ^{125} I-transferrin bound to $20,900 \pm 3,160$ (mean $\pm$ SD, $n = 4$) sites per cell on parenchymal cells with a K_d of $2.6 \pm 0.8 \times 10^8$ l mol⁻¹ (mean $\pm$ SD, $n = 4$). In the nonparenchymal cell fraction transferrin bound to $5,500 \pm 1,520$ (mean $\pm$ SD, $n = 3$) sites per cell with a K_d of

Fig 5. Frequency diagram of the microdensitometric absorbance (430 nm) of anti-human transferrin antibody peroxidase-anti-peroxidase (PAP) on random clusters of (A) nonparenchymal cells and (B) hepatocytes; 380 nonparenchymal cells and 350 hepatocytes were scanned. When the absorbance values were corrected for nonspecific staining, 40% of the hepatocytes and 60% of the nonparenchymal cells gave no measurable absorbance. Shown are the values for the remaining cells giving detectable absorbance.

Fig 6. Concentration-dependent binding of human ^{125}I -transferrin to purified (A) hepatocytes and (B) nonparenchymal cells at 4°C . Up to 3×10^6 cells were incubated in 0.5 mL of Hanks' balanced salt solution, 1% bovine serum albumin with 0.1 to 20 $\mu\text{g}/\text{mL}$ of transferrin for 90 minutes under air, 5% CO_2 . Cells were washed three times in phosphate-buffered saline at 4°C and counted in a γ counter. Specific binding ($\bullet$) was calculated by correcting total binding for nonspecifically bound counts ($\circ$) determined in the presence of 100-fold excess of unlabeled transferrin.

$3.3 \pm 1.9 \times 10^8 \text{ l mol}^{-1}$ (mean $\pm$ SD, $n = 3$). At saturation, nonspecific binding was 15% of the total binding in the parenchymal cell fraction and 20% of that in the nonparenchymal cell fraction. To investigate transferrin binding sites in a competitive setting, ^{125}I -human transferrin was added to purified parenchymal and nonparenchymal cells and either unlabeled human or rat transferrin was used to compete for binding. As shown in Table 1, similar numbers of binding sites were detected using this procedure as compared with the method used in Fig 7, with approximately four times more binding sites demonstrated on parenchymal cells than on nonparenchymal cells.

The above studies using intact cells at 4°C provide an estimate of the number of transferrin binding sites present on the external plasma membrane. To estimate the total number of receptors, assays were performed on extracts of cells

Fig 7. Scatchard²⁷ analysis of the binding data shown in Fig 6. In the experiment shown, the slope (K_d) for the hepatocytes ($\circ$) is equal to $3.4 \times 10^8 \text{ l mol}^{-1}$, and the value of the intercept with the abscissa indicates that 16.2×10^3 molecules of transferrin were associated with each cell. For the nonparenchymal liver cells ($\bullet$) the slope is $5.1 \times 10^8 \text{ l mol}^{-1}$ and the number of molecules bound was 3.8×10^3 per cell.

Table 1. Transferrin Binding Sites on Intact Cells at 4°C

Competing Ligand*	Parenchymal	Nonparenchymal
Human	$14,300 \pm 6,700$	$3,560 \pm 1,820$
Rat	$22,100 \pm 4,320$	$4,700 \pm 1,760$

Data are expressed as mean $\pm$ SD binding sites per cell. Cells were derived from three perfusions and fractionated by differential centrifugation as described in the Materials and Methods section.

*A fixed amount of ^{125}I -diferric human transferrin was added, and unlabeled transferrin (0 to 0.5 mg/mL) was added to compete for binding.

that had been solubilized in a detergent buffer. This treatment permeabilizes the cells and renders intracellular receptors available for binding as well as those present on the cell membrane.²⁰ With this technique, transferrin bound to $42,000 \pm 18,330$ (mean $\pm$ SD, $n = 3$) sites per cell in the parenchymal fraction and $14,760 \pm 7,120$ ($n = 3$) sites per cell in the nonparenchymal fraction.

DISCUSSION

The use of differential centrifugation¹¹ and colloidal silica (Percoll) gradient centrifugation¹² enabled us to prepare highly purified preparations of parenchymal and nonparenchymal cells from rat liver perfusates. This treatment is unlikely to have altered the characteristics of the cells significantly since they retained high viability ($> 90\%$) in both fractions and previous work²⁹ has shown that Percoll does not change the surface properties of isolated liver cells.

The hepatocyte is well established as the major site of transferrin synthesis³⁰, to avoid cross-reaction between endogenous transferrin and the antitransferrin antibody³¹ used during the immunocytochemical localization of receptor-bound ligand, we used human transferrin to occupy the receptors and its antibody, which did not react detectably with rat transferrin. Evidence for the specificity of this system came from the finding that staining could be abolished by occupying the receptors with rat transferrin and also by using human apotransferrin as ligand since at physiologic pH the iron-free form of transferrin has low affinity for its receptor.^{8,32} Because of this dependence on human transferrin, experiments were performed to characterize and compare the binding of human and of rat transferrin to the receptor on rat reticulocytes. Equilibrium binding experiments indicated that diferric human transferrin bound with high affinity to the rat receptor; furthermore, it bound with higher affinity than did rat transferrin. This difference in affinity was confirmed by the finding of at least a tenfold difference in the concentration of human ($6.9 \times 10^{-8} \text{ mol/L}$) and rat ($4.3 \times 10^{-7} \text{ mol/L}$) diferric transferrin required to displace 50% of ^{125}I -labeled human transferrin from rat reticulocytes. In contrast, both human and rat apotransferrins bound with an affinity ~ 1 order of magnitude less than the diferric proteins. This finding is in agreement with previous data showing very low binding affinity between the homologous apotransferrin and rabbit reticulocytes¹⁸ and rat liver cells.⁴

The present study provides morphological and biochemical evidence that human transferrin bound to receptors on

parenchymal as well as on nonparenchymal cells of rat liver. Intensity of staining showed individual variation, however, due to the specific binding of transferrin, as assessed visually and by microdensitometry, suggesting that some hepatocytes could express several times more receptors than the average number found using the radio-binding assays. The average of 20,000 surface receptors is in agreement with a previous report from this laboratory¹⁹ in which hepatocytes that had not undergone extensive purification to rid the parenchymal cells of contaminating nonparenchymal cells were used and rat transferrin was the ligand. The amount of transferrin bound in the present study, in which the titrations were done at 4 °C, was ~50% that reported previously for rat hepatocytes³⁻⁵ in which the analyses were performed at 37 °C. At the lower temperature, only surface receptors are occupied by ligand, whereas at 37 °C, endocytosis occurs and the full cellular complement of receptors is occupied.³³ Confirmation of the presence of a large intracellular pool of transferrin receptors in hepatocytes, as has been described for other types of receptor such as that for asialoglycoproteins,³⁴ was obtained from binding assays performed on permeabilized cells. This method showed that the total receptor number was >40,000 per cell.

Approximately 35% of the cells in the nonparenchymal fraction were peroxidase positive (Kupffer cells), a proportion similar to that observed in the intact liver,¹⁴ and it is likely that the separation techniques used here produced a representative population of nonparenchymal cells. Although we cannot comment at this stage on the distribution of transferrin receptors on different subpopulations of nonparenchymal cells, it is of interest that ~60% of these cells showed negligible binding of transferrin, suggesting (as with the hepatocytes) that an individual cell could have more receptors than the average found on this mixed population (surface ~5,000; total ~15,000) using the biochemical assays.

Despite the differences in receptor numbers expressed by the parenchymal and nonparenchymal cells, both bound transferrin with high affinity and similar association constants, which suggests that the cells express the same type of receptor. The values for the association constants obtained fall within the range reported for a variety of cultured cell lines^{32,33} as well as normal cells.³⁵

The finding that parenchymal cells have approximately three times the number of surface and total receptors as nonparenchymal cells is corroborated by the immunocytochemical demonstration of the binding of transferrin to the two cell types. Although the technique of microdensitometry cannot be used for the absolute quantitation of ligand binding, a comparison of the median absorbance range of the color reaction suggests that approximately three times more transferrin was bound by hepatocytes than by nonparenchy-

mal cells. We interpret the data showing heterogeneity of the color reaction between individual hepatocytes as indicating differences in receptor densities and the absence of transferrin binding to a proportion of hepatocytes and nonparenchymal cells as indicating that some cells express so few receptors that they are not detected by the techniques used here. Although transferrin receptors are maximally expressed by proliferating cells,^{36,37} this is unlikely to be the cause of receptor heterogeneity among hepatocytes, because the proportion of cells in the liver undergoing cell division is very small.³⁸ The heterogeneity may reflect different roles in iron metabolism of hepatocytes from different parts of the lobule, as has been shown for other hepatic functions.³⁹ Despite a recent claim to the contrary,⁴⁰ selective proteolytic damage to the transferrin receptors is unlikely since the perfusion buffers included a trypsin inhibitor⁴ and heterogeneity of staining was also seen on mechanically separated hepatocytes that had not been exposed to proteases. A study of the distribution of ferritin among individual hepatocytes would be of interest since it has been shown recently that there is an inverse relationship between the concentration of ferritin protein and expression of transferrin receptors by cultured human cells.²⁰

Our results do not substantiate the claim of Kishimoto and Tavassoli that transferrin receptors are expressed only by the nonparenchymal and specifically the endothelial cells of rat liver. This conclusion was based on their finding that ¹²⁵I-rat transferrin-coated minibeads failed to bind to isolated rat hepatocytes but were apparently specifically bound by endothelial cells. The uptake of minibeads could be a reflection of the accessibility of transferrin receptors on the different cell types since the membrane of endothelial cells is smooth, permitting access of immobilized ligand to its receptor. This contrasts with the more irregular membrane of the hepatocytes and Kupffer cells, which could compromise accessibility of ligand immobilized on relatively large beads. As discussed above, more recent claims by those workers that surface transferrin receptors are damaged by collagenase⁴⁰ are also unlikely, as we found that receptors were detectable on hepatocytes isolated by collagenase perfusion as well as by mechanical means. The concentration of ¹²⁵I-transferrin required to achieve saturable binding to liver cells in the studies of Kishimoto and Tavassoli was in excess of 1 μmol/L, which is in contrast to the results of the present study and to the experience of many workers using crude suspensions of hepatocytes³⁻⁵ and cultured cells^{20,32,33} in which saturation was achieved in concentrations ~1 order of magnitude less.

In conclusion, our finding that hepatocytes express, on average, three to four times more receptors than do nonparenchymal cells supports the concept that the hepatocyte has a central role in the uptake and storage of transferrin iron.

Human Acute Unclassified Leukemia With a Unique t(4;17) Chromosomal Translocation Expresses T Lymphoid and Myeloid Surface Antigens After In Vitro Culture

By Arnold Ganser, Gerhard Heil, Thomas Böhm, Claus R. Bartram, Anand Raghavachar, Felix Carbonell, and Dieter Hoelzer

Bilineage differentiation along both the T lymphoid and the myeloid lineage while in vivo diffusion chamber (DC) and in vitro suspension culture was observed in a case of acute unclassified leukemia (null-AL) and t(4;17). Prior to culture, the blast cells were TdT and Ia positive but did not express any lineage-specific antigenic markers. Furthermore, the immunoglobulin heavy chain and T cell receptor β -chain genes were in germline configuration. Cytogenetically, all metaphases had the unique translocation t(4;17) (q25;q23) prior to and after culture, supporting the leukemic origin of the cells. During both DC culture and suspension culture with and without tetradecanoyl-phorbol-acetate (TPA), a substantial increase in the absolute and relative number of cells expressing both myeloid and T lymphoid antigenic

markers occurred. Double-fluorescence analysis demonstrated the expression of antigenic markers of both lineages on the same population of cells, and electron microscopy revealed the induction of myeloperoxidase after both DC and suspension culture. Immunoglobulin heavy chain and T cell receptor β -chain genes remained in germline configuration after treatment with TPA, when analyzed with JH and CT β probes, respectively. These findings indicate that this case represents a null-AL with dual-lineage capabilities, which has probably arisen from the malignant transformation of a bipotential stem cell of lymphoid and myeloid progeny.

©1987 by Grune & Stratton, Inc.

SEVERAL recent reports have shown that in rare instances acute leukemic blast cells may express morphological, cytochemical, immunologic, or molecular genetic features of both the T lymphoid and one of the myeloid lineages.¹⁻⁶ Rapid conversion from a T lymphoid to a myeloid phenotype during treatment further supported the hypothesis that in some of these cases the leukemia arose from a multipotent stem cell capable of both lymphoid and myeloid differentiation.^{3,5,6}

We report a case of null-AL with the unique karyotype 46,XY,t(4;17) that originally did not exhibit any features of commitment. The cells were capable, however, of expressing markers of the myeloid and T lymphoid lineage after diffusion chamber (DC) and suspension culture without and with 12-O-tetradecanoyl-phorbol-acetate (TPA).

MATERIALS AND METHODS

Patient. On initial examination, a 64-year-old man had a leukocyte count of 400,000/ μ L with 98% blasts. His bone marrow was packed with blast cells. The blasts were negative for myeloperoxidase, α -naphthyl acetate esterase (ANAE), periodic-acid Schiff (PAS), and acid phosphatase. They were TdT positive but negative for lineage-specific surface markers. The diagnosis of null-AL was made. The patient died of cerebral leukostasis 1 week after an initial dose of 2 mg of vincristine intravenously (IV) and 35 mg of prednisolone three times daily orally.

Cells. After informed consent was given by the patient, leukemic blast cells were isolated from the peripheral blood by separation on a Ficoll-Hypaque gradient (1.077 g/mL) enriching the percentage of blast cells to >99%. The cells were cryopreserved in 10% dimethylsulfoxide at -196°C in liquid nitrogen prior to the present studies.

Diffusion chamber technique. The DC technique has previously been described.^{7,8} In brief, DC filled with 7.7×10^5 cells were implanted into CBA/Ca mice that had been given 7.5 Gy whole body X-irradiation. The chambers were harvested by shaking for 30 minutes in 0.5% pronase B (Merck, Darmstadt, FRG) in buffered Hank's solution to liquefy the clot. The resulting single-cell suspension harvested from 8 to 14 chambers at each interval was pooled. Smears were made for differential counts, and the remaining cells were used for immunological analysis. Cells to be used for surface marker analysis after being harvested from DC were further incu-

bated in Iscove's modified Dulbecco's medium (IMDM) supplemented with 5% heat-inactivated fetal calf serum (FCS) (Conco Laboratories, Wiesbaden, FRG) for 2 hours at 37°C in 5% CO_2 . The incubation in pronase needed for harvesting the chamber cells had no effect on the expression of the antigens examined and evaluated in the present experiments, as tested with positive and negative controls.

Suspension culture. The leukemic cells were cultured in vitro for 3 and 6 days at 1×10^6 cells/mL in RPMI-1640 supplemented with 50 μ mol/L of 2-mercaptoethanol, 10% heat-inactivated FCS, 2 mmol/L of glutamine, and antibiotics at 37°C in a 5% CO_2 humidified atmosphere. TPA (Sigma, St Louis) dissolved in ethanol at 10^{-5} mol/L was stored at -20°C and diluted in culture medium just before use to give a final concentration of 5×10^{-9} mol/L. The final concentration of ethanol in the control cultures was <0.1%. At the end of the incubation period, aliquots were taken for enumeration of viable cells by trypan blue exclusion and for phenotypic analysis.

Phenotypic analysis with antibodies. Phenotypic analysis was performed with the cells settled onto glass slides coated with poly-L-lysine.⁹ Attached cells were fixed for 7 minutes in glutaraldehyde (0.05% in 0.1 mol/L of phosphate buffer, pH 7.4) at 4°C followed by 10 minutes in 0.3 mol/L of glycine buffer. The cells were then tested with monoclonal antibodies against differentiation antigens of the various cell lineages: OKIa1 against HLA-DR¹⁰; the T

The cluster designations (CDs) are those recommended at the First and Second International Workshops on Human Leukocyte Differentiation Antigens.³⁰

Binding of antibodies to target cells was revealed by the immunalkaline phosphatase method³¹ using goat-anti-mouse Ig coupled to alkaline phosphatase (Sigma, 1:40) as second antibody. Isotype-identical nonreactive mouse monoclonal antibodies served as controls. Cytoplasmic μ chains were detected by a modification of the method of Vogler and colleagues³² using a monoclonal antibody against μ chains (P.M. Lansdorp, Amsterdam) and the alkaline phosphatase antialkaline phosphatase (APAAP) technique. Reagents used as sandwich antisera in the APAAP technique consisted of the goat-anti-mouse Ig coupled to alkaline phosphatase (Sigma, 1:20) and the APAAP complex from the mouse (Dakopatts). TdT was assayed by a modification of the method of Bollum.³³ The reagents for the terminal deoxynucleotidyl transferase (TdT) assay were purchased from BRL (Gaithersburg, MD); 200 cells were examined in each test.

Double-fluorescence analysis. Double-fluorescence immunologic phenotyping was done prior to and after DC and suspension culture, using the antibodies VIM-2, WT1, and OKT6. Cells were first labeled with the myeloid antibody VIM-2 and counterstained with TRITC-conjugated, affinity-purified F(ab')₂ fragment goat-anti-mouse IgM (μ chain-specific, dilution 1:20; Zymed Laboratories, Wiesbaden, FRG), followed by incubation with the T lymphoid markers WT1 or OKT6 and counterlabeling with FITC-conjugated, affinity-purified F(ab')₂ fragment goat-anti-mouse IgG (Zymed). The fluorescence of the cells was examined under a Leitz microscope with epifluorescent illumination and equipment for the dual-wavelength method; 200 cells were examined in each test.

Cytogenetic analysis. Cytogenetic analysis was performed before and after DC and suspension culture as already described,³⁴ using GTG-banding.

Immunoglobulin heavy chain and T cell receptor β chain gene rearrangements. DNAs were extracted from mononuclear cells after Ficoll-Hypaque centrifugation by standard techniques. DNA 15 μ g was digested with appropriate restriction enzymes (Boehringer Mannheim), electrophoresed on a 0.7% agarose gel, and blotted and hybridized as described.^{35,36} λ -DNAs were included as mol wt markers. Bgl/II digests were hybridized to a JH probe (Oncor, Gaithersburg, MD), which detects a 5.0-kilobase (kb) heavy chain Ig gene germline fragment. BamHI digests were hybridized to a C τ β probe (Oncor) that detects a 23-kb germline band of the T cell

receptor β chain gene. Probes were handled under P2EK1 containment according to the National Institute of Health Guidelines for research involving recombinant DNA molecules. After hybridization, the filters were washed under stringent conditions and exposed to XAR-5 film (Kodak) using Dupont Lightning-Plus intensifying screens for 12 to 48 hours at -70°C .

Electron microscopy. Ultrastructural analysis for the detection of peroxidase was done on cells that were either unfixed³⁷ or fixed in glutaraldehyde³⁸ prior to incubation in 3'-3'-diaminobenzidine (DAB) and H₂O₂. For controls, either DAB or H₂O₂ was omitted from the incubation mixture. The processing for transmission electron microscopy was carried out as described by Polli and colleagues.³⁹ Sections were viewed unstained according to usual procedures.

In situ hybridization. According to published protocols,⁴⁰ chromosomes were treated with RNase and denatured in 70% formamide/2 $\times$ SSC at 70°C for 2 minutes. Probes were nick-translated using ³H-dCTP and ³H-dTTP (NEN, Boston) to a specific activity of 1.9×10^7 cpm μg^{-1} , denatured for 5 minutes at 70°C in 50% formamide/2 $\times$ SSC/10% dextran sulfate and hybridized for 12 hours at 37°C ; slides were rinsed in 50% formamide/2 $\times$ SSC followed by extensive washings in 2 $\times$ SSC and exposed to Kodak NTB 2 emulsion for 10 days at 4°C , developed, and stained with quinacrine mustard. The probe used was a 1.8-kilobase (kb) EcoRI p53 cDNA clone (p53-H13).⁴¹

RESULTS

Prior to in vitro culture, the leukemic blast cells did not express lineage-specific markers but were positive for OK1a and the stem cell marker RFB-1. The T cell marker WT-1 was positive in <5% and the myeloid marker MY-7 was positive in <15% of the cells. Morphologically, the blast cells were undifferentiated, with occasional to moderate numbers of nucleoli. The cytochemical reactions were negative; ultrastructurally, no myeloperoxidase or platelet peroxidase was detectable (Figs 1a and 2a). The cells were TdT-positive, however. Southern blot analysis of the immunoglobulin and the T cell receptor genes showed no rearrangement within the immunoglobulin μ gene and the T cell receptor β chain sequences covered by the probes used (Fig 3). Cytogenetic analysis revealed a t(4;17)(q25;q23) translocation in all 25 metaphases analyzed (Fig 4). After hybridization of human p53 sequences to 43 metaphases, 153 grains were observed on chromosomes. The distribution of the silver grains was uniform and random on all chromosomes, except for specific signals ($P < .001$) on chromosomes 17 (18 grains v 2.4 grains expected) and 17q+ (21 grains v 3.1 expected); 21% of grains clustered on region 17p13 on both chromosomes.

The cells were cultured using two different types of culture systems. During DC culture, the total number of cells increased substantially, rising from 3.85×10^6 cells/mL ($7.7 \times 10^5/\text{DC}$) to 8.5×10^6 cells/mL ($17.0 \times 10^5/\text{DC}$). After 14 days of DC culture, 17.8% of the cells could be morphologically identified as belonging to the granulopoietic lineage (Table 1). There was a rapid loss of the marker RFB-1, followed by a relative and absolute increase in the number of cells expressing MY-7, VIM-2, B4.3, B13.9, MY-4, and OKM-1 (Table 2). The cells expressing the T-marker WT1 also increased steadily, whereas the number of cells reactive with OK1a and those carrying the transferrin

Fig 1. Ultrastructural morphology of the blast prior to (A) and after (B) culture. Prior to cultures the blasts have the morphology of undifferentiated, lymphoblastlike cells with several prominent nucleoli (N) lacking morphological features of myelomonocytic differentiation (lead citrate stain, original magnification $\times 12,000$; current magnification $\times 9,000$). After culturing, the nucleus becomes more indented. The enlarged cytoplasm contains many mitochondria and several vesicles; some contain electron-dense inclusion bodies (arrow in b). No azurophilic granules are visible. (N, nucleolus; lead citrate stain; original magnification $\times 10,000$; current magnification $\times 7,500$).

Fig 2. Ultrastructural cytochemistry (platelet peroxidase [PPO] reaction) of the blast cells, unstained sections. (A) Prior to culture the blast cells are undifferentiated, only a nonspecific peroxidase reaction can be seen in the mitochondria (arrow) due to oxidative phosphorylation enzymes (original magnification $\times 12,600$; current magnification $\times 9,450$). (B) After exposure to tetradecanoyl-phorbol-acetate (TPA) for 3 days, the blast cells developed the characteristic pattern of peroxidase activity of myeloblasts: reactivity is seen in the nuclear envelope, in the endoplasmic reticulum, and in the Golgi cisternae (arrow). The two large dark staining spots represent fat droplets in the cytoplasm (original magnification $\times 13,000$; current magnification $\times 9,750$).

receptor decreased both in absolute and relative numbers during the culture period.

During suspension culture, the cells retained their blast-like morphology; however, $\sim 25\%$ of the cells developed focal acid phosphatase positivity under either condition, whereas no myeloperoxidase was detected at the light microscope level. The number of cells staining with MY-7 (Table 3) increased substantially within 24 hours (data not shown). Another myeloid marker, VIM-2, also developed. When the cells were exposed to TPA, the pan-T marker WT1 and the IL-2 receptor (Tac) were newly expressed, followed by early (OKT6) and late (OKT3, OKT4) T cell markers, as well as BA-2. A proportion of cells (25%) also became focally

Fig 3. Southern blot analyses of immunoglobulin heavy chain and T cell receptor β chain rearrangements before (–) and after (+) suspension culture in presence of tetradecanoyl-phorbol-acetate (TPA). DNAs from leukemic cells were analyzed for IgH and T β rearrangements after digestion with *Bgl*II and *Bam*HI, respectively, using the probe indicated at the bottom of each blot. The numbers at the side of the lanes are the size of fragments in kilobases.

positive when stained cytochemically for acid phosphatase. Again no myeloperoxidase was observed at the light microscope level, however. The phenotype of the cells then was MY-7+, VIM-2+, BA-2+, OKT6+, OKT3+, OKT4+, B3/25+, OKIa+ (Table 3). No B lineage-specific markers were expressed under any culture conditions. Simultaneous staining using double-immunofluorescence revealed that after culture with TPA both myeloid and T lymphoid markers were expressed on the same population of cells (Table 4).

Because the cells were Tac-antigen positive after exposure

to TPA, the cells were then further incubated with either IL-2 or concanavalin A, alone, or in combination for another 4 days. No further increase in cell number was observed after either culture, however (data not shown).

Ultrastructural analysis revealed that although the cells were negative prior to culture, >80% expressed peroxidase activity in the nuclear envelope, the endoplasmic reticulum, and the Golgi apparatus after DC culture and after suspension culture with TPA (Fig 2b). When the cells were analyzed cytogenetically, only pseudodiploid metaphases with the karyotype 46,XY,t(4;17) (q25;q23) were found after any of the various cultures. The immunoglobulin heavy chain and the T cell receptor β chain gene regions remained in the germline configuration when probed with the respective probes (Fig 3), after exposure of the cells for 4 days to TPA in suspension culture.

DISCUSSION

Several characteristics of the cells prior to and after culture indicate that in this case the malignant transforma-

tion could have taken place in a cell capable of myeloid and T lymphoid differentiation: the initial expression of RFB-1, a marker found on hemopoietic progenitor cells and very immature T cells but not on B lineage cells,²⁴ the induction of both T lymphoid and myeloid markers, the induction of focal expression of acid phosphatase and, finally, the induction of myeloperoxidase. The occurrence of a malignant translocation at this level has been previously postulated by the findings of rapid switches from T-ALL to acute myeloid leukemia.^{3,5,6,42}

The present case differs from previous cases of multilineage differentiation⁴³ by the absence of differentiation markers on the cells prior to culture. An unusual differentiation capacity was revealed by both the in vivo and in vitro culture systems, however. During DC culture, which allows maturation along the myeloid^{7,8} and lymphoid lineages,⁴⁴ the cells not only expressed several markers of the myeloid as well as the T lymphoid lineages, but also partially differentiated to morphologically recognizable granulocytic cells. Differentiation toward the myeloid lineage was supported by transmission electron microscopy, demonstrating the presence of

myeloperoxidase in the blast cells after DC culture as well as after exposure to TPA in suspension culture.⁴⁵

Although the induction of T cell markers, including the thymic marker OKT6, is very unusual and to our knowledge has never been found in a case of null-AL before,^{46,47} there has been a case of acute myeloid leukemia that expressed WT-1 before and OKT6 after in vitro culture.⁴⁸ This was interpreted as lineage infidelity with aberrant expression of lymphoid surface antigens on myeloid cells; however, the apparent similarity to our case suggests a capacity for bilineage differentiation in both cases.

Evidence that both myeloid and T lymphoid markers were coexpressed on a significant proportion of the blast cells was provided by expression of the myeloid markers MY-7 and OKM-1 on nearly all and of WT-1 on about one-third of the cells after DC culture. Further evidence is given by the results of the double-labeling analysis after suspension culture, which demonstrated the coexpression of both the myeloid marker VIM-2 and the T lymphoid markers WT-1 and OKT6 on the same blast cell population.

Because WT1 can occasionally be found on leukemic cells of the myeloid lineage,⁴⁹ it was of importance that further T-cell markers OKT6, OKT3 and OKT4¹² were inducible by TPA in suspension culture. That the immunoglobulin heavy chain and T cell receptor β chain gene regions remained in the germline configuration after exposure to TPA and that T cell marker appeared on the surface of treated cells indicates that no clonal D-J joining events occurred in these cells after induction of differentiation with TPA.

The proliferation of normal cells from the peripheral blood is largely excluded by cytogenetic analysis before and after culture, by the coexpression of myeloid and T cell markers on the same cells, and by the expression of OKT6.⁵⁰ Although cytogenetic analysis provides the karyotype of only a small number of cultured cells, the remote possibility that cells other than those with t(4;17) could have contributed to the unique marker expression can be largely ruled out. This

Table 4. Expression of Myeloid (VIM-2, MY-7), T Lymphoid (WT-1, OKT6), and IL-2 Receptor (Tac) After Exposure to 5 nmol/L of TPA for 72 hours as Determined by Double Fluorescence

Monoclonal Antibodies	Positive Cells (%)
VIM-2	65

VIM-2 + Tac	37

IL-2, interleukin-2; TPA, tetradecanoyl-phorbol-acetate.

would imply a rapid increase in cell number, which should have been detected by cytogenetic analysis.

The observed chromosomal translocation allows a provocative speculation about the role of chromosomes 4 and 17 in the present and other cases of bilineage differentiation. A translocation with a breakpoint on chromosome 4, ie, t(4;11), has been described in acute leukemia of unclassified phenotype,^{51,52} in acute lymphoblastic leukemia,⁵³ and in acute leukemias with both myeloid and lymphoid features.^{54,55} In addition, the breakpoints on chromosomes 4 and 17 have both been described in a case of null-AL and variant translocation t(4;11;17).⁵⁶ Thus, the possibility that these chromosome regions are of importance, perhaps related to an

oncogene, is intriguing. Although involvement of the gene for p53 could be ruled out in concordance with a recently published report,⁵⁷ the significance of the gene for erb A located on the long arm of chromosome 17⁵⁸ or the gene coding for IL-2 on chromosome 4⁵⁹ remains an area for further investigations.

ACKNOWLEDGMENT

We would like to thank Drs M.P. Bodger, W. Knapp, P.M. Lansdorp, W. Tax, and T. Waidmann for providing monoclonal antibodies and Dr V. Rotter for the p53 probe. The excellent technical assistance by A. Forstner, R. Geiger, G. Kepes, and M. Leonhard is gratefully acknowledged.

Platelet Surface-Bound IgG in Patients With Immune and Nonimmune Thrombocytopenia

By Wayne S. Court, Joyce M. Bozeman, Seng-jaw Soong, Mansoor N. Saleh, Denise R. Shaw, and Albert F. LoBuglio

We quantitated the amount of platelet surface-bound IgG using an ^{125}I monoclonal anti-IgG assay in 149 patients with thrombocytopenia and 260 normal donors. The normal subjects had 122 ± 5 molecules of IgG/platelet (mean $\pm$ SE). Fifty-five patients with nonimmune thrombocytopenia had 338 ± 37 molecules of IgG/platelet, whereas 67 patients with immune thrombocytopenia studied at the time of their initial evaluation had $4,120 \pm 494$ molecules of IgG/platelet. An analysis of the distribution of values in these two groups indicated that 90% of the patients with immune thrombocytopenia had >800 molecules of IgG/platelet, whereas only 7% of patients with nonimmune thrombocytopenia exceeded this amount. The immune thrombocytopenic patients included 39 idiopathic, 14 secondary, and 14 drug-induced disorders, and they did not significantly differ in their distribution of values for platelet IgG. The nonimmune thrombocytopenic patients included 12 cases with a platelet destructive mechanism; their

platelet-bound IgG was similar to that of the other nonimmune patients. Twenty-seven patients with treatment-resistant immune thrombocytopenia were also studied; they had $2,100 \pm 670$ molecules of IgG/platelet. Their values were significantly greater than those of the nonimmune thrombocytopenic patients and not significantly different from those of immune thrombocytopenic group. Their distribution of values was much broader, however, with 33% of patients having <800 molecules of IgG/platelet, suggesting possible alternate mechanisms in their thrombocytopenia. Thus, patients with immune thrombocytopenia have a high frequency of elevated IgG on the platelet surface which reflects the pathophysiology of this disorder. Quantitation of platelet-bound IgG provides a useful laboratory tool in the differential between immune and nonimmune thrombocytopenia.

IMMUNE thrombocytopenic purpura (ITP) in adults is a syndrome of shortened platelet survival with reticuloendothelial sequestration. This syndrome of accelerated platelet destruction appears to be mediated primarily by IgG antibody directed toward ill-defined platelet surface antigens.^{1,2} In the decade since Dixon and co-workers³ first documented elevated levels of platelet-bound IgG (PBIgG) in patients with ITP, a variety of assay techniques for measuring platelet IgG has been reported.⁴⁻¹³ These different assays use various methodologies and report elevated values for IgG associated with platelets in ITP. Elevated values have also been noted in thrombocytopenia presumed to be due to nonimmune mechanisms, however, resulting in the interpretation that such values are a nonspecific finding unrelated to the pathophysiology of immune platelet destruction.¹⁴⁻²⁰ Recent studies have clarified the limitations imposed by conventional competitive binding assays, using calibration by soluble IgG standards^{21,22} and the potential value of a direct binding assay using stoichiometric relationships. We have previously characterized and described such an assay using monoclonal ^{125}I anti-human IgG to quantify platelet surface-bound IgG.^{23,24} By means of this quantitative technique the amount of surface IgG displayed on the

platelet surface in a large group of thrombocytopenic patients was analyzed.

MATERIALS AND METHODS

Assay for platelet surface-bound IgG. The preparation of monoclonal ^{125}I anti-IgG reagent as well as the standard assay conditions are reported in detail elsewhere.²⁴ This antibody was originally generated by J. Donald Capra and was purchased from Bethesda Research Laboratory (MD), but is no longer available from this source. More recently, the hybridoma producing this antibody is available through the American Type Culture Bank (ATCC-HB-43), and purified antibody is commercially available. (Southern Biotechnology Associates, Birmingham, AL, catalogue no. 9040). In brief, venous blood was collected in plastic syringes and anticoagulated with acid citrate dextrose A. This method allows shipment of whole blood on wet ice with minimal effect on platelet IgG levels.²⁵ The whole blood was centrifuged at 200 g for 20 minutes, and the platelet-rich plasma was collected. The pH was adjusted to 6.5 with acid citrate dextrose A and then centrifuged at 1,750 g for 20 minutes. The platelet button was washed three times in platelet-suspension buffer (Dulbecco's phosphate-buffered isotonic saline containing 1 g/dL of bovine serum albumin (BSA) and 4 mmol/L of EDTA, pH 6.7). Ten million washed platelets were incubated with 300 ng of ^{125}I -labeled mouse monoclonal anti-IgG in a total volume of 300 μL for 20 minutes at room temperature. Triplicate aliquots of 75 μL (2.5×10^6 platelets) were transferred to Percoll gradient tubes containing 250 μL of isotonic 30% Percoll in saline, centrifuged at 7,500 g for 5 minutes, and the tube tip containing the platelet button was transected with a hemostat and razor blade into γ counting tubes. The number of ^{125}I monoclonal antibody molecules bound per platelet was calculated on the basis of Avogadro's number, the antibody's specific activity, and mol wt. We previously showed that with these assay conditions the stoichiometry of the binding reaction approaches unity and that the "nonspecific" binding of the monoclonal anti-IgG is $<5\%$.²⁴ Thus, the number of molecules of platelet-bound ^{125}I monoclonal antibody is equal to the number of molecules of platelet surface-bound IgG.²⁴

Patient characteristics. One hundred forty-nine thrombocytopenic patients with at least three platelet counts $<100,000/\mu\text{L}$ and 260 normal subjects comprised the study group. Sixty-seven of the patients were referred for evaluation at the time of initial diagnosis of immune thrombocytopenic purpura based on conventional clinical

*TTP, thrombotic thrombocytopenic purpura; MHA, microangiopathic hemolytic anemia; DIC, disseminated intravascular coagulation.

criteria (adult onset thrombocytopenia with normal to increased megakaryocytes in the bone marrow and no other explanation for thrombocytopenia found). Of this group, 39 were classified as idiopathic, 14 were secondary (7 systemic lupus erythematosus, 3 rheumatoid arthritis, and single cases of lymphoma, infectious mononucleosis, Evans syndrome, and AIDS), and 14 were drug-induced (11 quinidine and single cases with reserpine, mezlocillin, and chlorpropamide). These patients were studied prior to therapy or after no more than 48 hours of initiation of corticosteroids. Fifty-five patients had thrombocytopenia that was considered non-immune in origin, including nonimmune destructive thrombocytopenia in 12 patients (Table 1), aplastic anemia in 13, acute leukemia in 11, hypersplenism in 6, multiple myeloma in 3, metastatic cancer in 3, hereditary thrombocytopenia in 2, sepsis in 2, renal disease in 2, and paroxysmal nocturnal hemoglobinuria in 1 patient.

A third group of thrombocytopenic patients was classified as treatment-resistant ITP. These 27 patients had the criteria for idiopathic thrombocytopenic purpura, were treated extensively elsewhere, and were referred for evaluation because of persistent thrombocytopenia. All these patients had received weeks to months of corticosteroids, many had been splenectomized, and some had received immunosuppressive therapy.

Statistical analysis. The distributions of platelet-bound IgG values in various groups of thrombocytopenic patients and normal subjects were compared. The significance of the difference between any two of these distributions was determined by the Wilcoxon two-sample test. Sensitivity and specificity were calculated as measurements of the diagnostic ability of platelet-bound IgG to discriminate immune thrombocytopenia from nonimmune thrombocytopenia. The correlation coefficient and the significance of the correlation between platelet counts and platelet-bound IgG values were calculated using Spearman's method.

RESULTS

Our observations of platelet-bound IgG in various patients and normal groups is summarized in Table 2. In a group of 260 normal volunteers studied for a 2-year period, the mean amount of platelet-bound IgG was 122 ± 5 (mean $\pm$ SE) with a median of 92 molecules of IgG per platelet. The highest value recorded was 400 molecules of IgG per platelet. The 55 patients with nonimmune thrombocytopenia had higher mean (338 ± 37) and median (260 molecules per platelet) amounts of platelet-bound IgG that were significantly ($P < .001$) above that seen in normal controls by the Wilcoxon two-sample test (Table 3). There was a modest negative correlation of platelet count and platelet-bound IgG with a Spearman coefficient of correlation of -0.285 ($P = .037$).

As shown in Table 2, the patient groups of immune thrombocytopenia at the time of initial evaluation as well as the group of treatment-resistant immune thrombocytopenia had dramatically greater amounts of platelet-bound IgG than did either the normal donors or nonimmune thrombocytopenic patients. The patients with idiopathic, secondary, and drug-induced immune thrombocytopenia did not differ significantly from each other in regard to platelet-bound IgG values (Table 3). As a group or individually, however, they had significantly greater amounts of platelet-bound IgG than did patients with nonimmune thrombocytopenia or normal donors (Table 3).

Figure 1 examines the proportion of patients having various amounts of platelet-bound IgG. To differentiate between patients with immune thrombocytopenia v nonimmune, a cutoff value of 800 molecules of IgG per platelet provided the best sensitivity and specificity values. Sixty of 67 patients with immune thrombocytopenia at the time of initial evaluation had >800 molecules of IgG per platelet (sensitivity 90%), whereas 51 of 55 patients with nonimmune thrombocytopenia had <800 molecules of IgG per platelet (specificity 93%). Values of <400 molecules of IgG per platelet adequately describe the population of normal donors. Table 2 provides a breakdown of all patient groups according to these cutoff values. Thus, 90% of patients with immune thrombocytopenia had platelet-bound IgG >800 molecules of IgG per platelet whereas 7% of nonimmune thrombocytopenic patients had values above this cutoff.

The group of patients with nonimmune thrombocytopenia included 12 patients with thrombocytopenia due to premature destruction of platelets (nonimmune) and presumably increased platelet production similar to the platelet kinetics

Table 2. Platelet-Bound IgG in Thrombocytopenic Patients and Normal Donors

Nonimmune thrombocytopenia v normal donors	<.0001

Wilcoxon two-sample test was used for significance testing.

that exist in immune thrombocytopenia. As listed in Table 1, eight of these patients had thrombotic thrombocytopenic purpura. Their distribution of platelet-bound IgG was similar to that of the other nonimmune thrombocytopenic patients, with 67% in the normal range (<400), 25% between 400 to 800, and 8% (one patient) >800 molecules of IgG per platelet. This patient had received large volumes of plasma prior to referral to our institution, which may have influenced the result at the time of our study.

The group of patients with treatment-resistant immune thrombocytopenia had all been extensively treated prior to referral to our institution. This is obviously a highly selected subgroup of immune thrombocytopenia. As a group, their platelet-bound IgG was significantly greater than that of nonimmune thrombocytopenic patients or normal donors (Table 3). Their amount of platelet surface-bound IgG was almost significantly lower than that of the group of patients with immune thrombocytopenia, however ($P = .09$). In

addition, the values for platelet-bound IgG were more widely distributed than those of the patients studied at the time of initial diagnosis (Table 2 and Fig 2). A third of these patients had <800 molecules of IgG per platelet, whereas some of the patients had large amounts of IgG on their platelet surfaces (Fig 2).

Table 4 lists the characteristics of the patients whose platelet-bound IgG did not correlate with the clinical diagnosis of immune v nonimmune etiology. We were unable to discern any clinical parameters that characterized the patients with immune thrombocytopenia who had low platelet antibody values as compared with their counterparts with elevated values, including appropriate response to therapy. Three of the patients with nonimmune thrombocytopenia had values minimally >800 molecules of IgG per platelet cutoff, and the fourth patient had TTP with substantial plasma infusions prior to study.

Finally, as illustrated in Fig 3, we found no correlation between platelet count and platelet-bound IgG values in the 67 patients with immune thrombocytopenia ($r = -.063$, $P = .612$).

DISCUSSION

The controversy regarding the amount and pathophysiologic role of immunoglobulin associated with platelets from normal and immune thrombocytopenic patients is gradually being clarified. Using a variety of assay methods, most earlier studies suggested that normal platelets had large amounts of platelet-associated IgG (5,000 to 80,000 molecules per platelet) and even higher levels in immune thrombocytopenia.³⁻²⁰ These very large and seemingly nonphysiologic amounts of platelet-associated IgG have led some investigators to question the role of the IgG so measured in the pathophysiology of immune destruction.¹⁴⁻¹⁷ Some stud-

Fig 1. Proportion of patients with various amounts of platelet surface-bound IgG in normal and thrombocytopenic groups. The amounts of platelet surface-bound IgG are expressed as molecules of IgG per platelet (log scale).

ies have explored the result of differences in assay and calculation technique on estimates of platelet IgG. Rosse and colleagues²¹ and Blumberg and colleagues²² recently suggested that anti-IgG has 40 to 80 times the affinity for surface-displayed IgG as compared with soluble IgG, thus accounting for the very high values of platelet IgG when competitive binding assays calibrated with soluble IgG standards are used. Another tenable hypothesis is that certain assays purposely or inadvertently^{9,12,13,26} cause platelet lysis or release of canalicular entrapped plasma, resulting in measurement of both surface and "intracellular" IgG. In this regard, we used the monoclonal anti-IgG assay to demonstrate that the normal platelet surface displays only a few hundred IgG molecules but that platelet lysates have large amounts (20,000 to 80,000 molecules of IgG per platelet), comparable to results of prior reports.²⁴ To provide truer

estimates of platelet-bound IgG, certain assay techniques directly measure anti-IgG binding and use stoichiometric calculations to quantify platelet surface-bound IgG. These reports include the monoclonal anti-IgG assay,^{21,23,24,27} staphylococcal protein A assay,²⁸ and an assay using a polyclonal anti-IgG.¹¹ All these studies demonstrate that normal platelets have relatively little surface IgG, and amounts ranging from 500 to 13,000 molecules of IgG per platelet are present in immune thrombocytopenia. These amounts of platelet surface-bound IgG are similar to the values seen in the well-studied pathophysiology of warm immune hemolytic anemia.^{29,30}

Of these techniques, we believe that the monoclonal anti-IgG assay has several advantages. First, the monoclonal anti-IgG reacts equally with all four subclasses of IgG,²⁴ whereas staphylococcal protein A reacts poorly or not at all with IgG₃ and the polyclonal reagent has not been characterized and may vary with each antiserum produced. Second, the monoclonal anti-IgG has a very high binding affinity,^{24,27}

allowing saturation kinetics to be reached at low protein concentrations (1 ng/ μ L) under our assay conditions, resulting in little or no nonspecific anti-IgG association with the platelet surface.²⁴ Finally, the use of a single Percoll gradient centrifugation to separate platelet-bound from free anti-IgG precludes loss of platelets and disassociation of anti-IgG from IgG during repeated washing steps. The major drawback with this technique has been the relative unavailability of the monoclonal anti-IgG reagent. This is no longer a problem because the hybridoma cell line is available from the American Type Culture Bank (ATCC-HB-43) and from a commercial source of the purified antibody (Southern Biotechnology Associates).

In this study, we examined the amount of platelet surface-bound IgG in patients with thrombocytopenia due to immune and nonimmune etiologies. We showed that 90% of patients with immune thrombocytopenic purpura have increased amounts of surface-bound IgG (>800 molecules of IgG per platelet) at the time of initial diagnosis with a range of 87% to 93% for the various subgroups (Table 2). In contrast, patients with nonimmune thrombocytopenia infrequently had elevations of this degree (7%) indicating that quantitation of platelet surface-bound IgG can be a valuable adjunct in the evaluation of thrombocytopenic patients. Prior reports have indicated that patients with TTP have elevated platelet associated IgG.^{14,31} Our experience in eight patients failed to confirm this observation: only one patient had an elevated value, which was suspect because of prior exposure of the patient to large amounts of pooled plasma before being referred for study. Indeed, the patients with nonimmune thrombocytopenia associated with enhanced platelet destruction (and presumably enhanced platelet production) had low amounts of platelet-bound IgG, similar to those of other nonimmune thrombocytopenic disorders.

The group of patients with treatment-resistant immune

thrombocytopenia differed from their counterparts at initial diagnosis in that a larger proportion of them (33%) had values of platelet surface IgG comparable to those of normal donors or nonimmune thrombocytopenia patients. This may reflect the role of other pathophysiologic processes, including IgM, complement, or nonimmune mechanisms.

Two caveats to interpretation of platelet-bound IgG values in thrombocytopenic patients should be noted. Patients with immune thrombocytopenia who have been on therapy for >48 hours, usually with rising platelet counts, may have normal platelet-bound IgG values. Conversely, patients with acute leukemia who are severely ill and are receiving multiple antibiotics and platelet transfusions often have elevated values, the mechanisms of which are unknown but may be multifactorial. We have excluded both of these groups from our analysis and do not recommend interpretation of platelet-bound IgG values in these circumstances.

Finally, studies carried out in our laboratory³² using normal platelets sensitized in vitro with an IgG anti-PIA₁ antibody indicated that human monocytes have a threshold of ~1,000 molecules of IgG per platelet for recognition and binding of IgG-coated platelets through their Fc receptors. This is certainly compatible with the degree of sensitization observed in this study of platelets sensitized in vivo (ITP) resulting in presumed macrophage binding in splenic sinusoids.

Thus, this study indicates that patients with immune thrombocytopenia have a high frequency of elevated amounts of platelet surface-bound IgG as compared with patients with nonimmune thrombocytopenia. Quantitation of surface-bound IgG represents a clinically useful tool for delineating an immune etiology related to IgG on the platelet surface. The finding of elevated platelet-bound IgG by this monoclonal anti-IgG technique certainly appears to be of pathophysiologic relevance.

Measurement of Free, One-Chain Tissue-Type Plasminogen Activator in Human Plasma With an Enzyme-Linked Immunosorbent Assay Based on an Active Site-Specific Murine Monoclonal Antibody

By P. Holvoet, J. Boes, and D. Collen

An enzyme-linked immunosorbent assay for free tissue-type plasminogen activator (t-PA) in human blood was developed based on a murine monoclonal antibody directed against the active site of t-PA. The lower limit of sensitivity of the assay applied to plasma is 2 ng/mL for one-chain t-PA but only 100 ng/mL for two-chain t-PA. Free t-PA in plasma taken at rest was found in 6 of 21 healthy subjects (4.5 ± 0.8 ng/mL, mean $\pm$ SD) and increased to 14 ± 7.0 ng/mL after venous occlusion in 18 of these individuals. A linear correlation between total t-PA and free t-PA was observed with $r = 0.92$ ($n = 18$) and a slope of 1.08,

indicating that t-PA released from the vessel wall circulates in the blood as the one-chain form. In 16 of 18 patients with deep vein thrombosis, the increase of total t-PA antigen after venous occlusion was comparable to that observed in controls, but the free t-PA was significantly lower or undetectable. The present assay for free t-PA may be useful for the investigation of the release and inhibition of t-PA under physiological, pharmacological, or pathological conditions in humans.

TISSUE-TYPE plasminogen activator (t-PA) constitutes a physiologically important pathway for the activation of the fibrinolytic system in blood.¹ Venous thrombosis is frequently associated with a reduced increase of plasminogen activator activity in the blood, following standard stimuli (eg, venous occlusion).^{2,3} This impaired fibrinolytic response may be due to the rapid inhibition of released t-PA by a potent fast-acting inhibitor of plasminogen activator (PA-inhibitor).⁴

In earlier studies, the measurement of the plasminogen activator activity in plasma relied on the measurement of the fibrinolytic activity in euglobulin fractions.⁵ Such assays lack specificity, however, because they are dependent on many factors, such as the concentration of plasminogen activators, plasminogen, fibrinogen, and inhibitors. More recently, functional assays more specific for t-PA were developed.^{6,7} In these relatively complicated assays, the presence of fibrin or fibrinogen/fibrin fragments is required, and the results depend on the adequate removal of inhibitors.

Immunoassays specific for t-PA have also been developed.⁸⁻¹⁴ Although these assays are very sensitive (allowing detection of t-PA in the pmolar range), they do not discriminate between functionally active and complexed forms of t-PA. Indeed, the observed increase in total t-PA antigen following venous occlusion in patients with venous thrombosis was not consistently associated with an increase in t-PA activity.^{11,14} In such patients, increased levels of the fast-acting inhibitor of plasminogen activator have been measured.¹⁵⁻¹⁷

Immunoassays that could discriminate between free (ac-

tive) and complexed (inactivated) t-PA antigen might be useful for a more detailed investigation of the release and inhibition of t-PA in blood, under physiological, pharmacological, and pathological conditions. In the present study, we developed an enzyme-linked immunosorbent assay (ELISA) specific for free t-PA in blood. This assay was applied to the study of the release and inhibition of t-PA following venous occlusion in plasma samples of healthy subjects and patients with deep vein thrombosis.

MATERIALS AND METHODS

Purified proteins. One-chain and two-chain t-PAs were purified from the culture fluid of human melanoma cells.¹⁸ The activity was expressed in international units by comparison of the fibrinolytic activity on plasminogen-enriched bovine fibrin films⁵ with that of the 1st International Reference Preparation of t-PA (83/517).¹⁹ The protein concentration of t-PA was determined by amino acid analysis.¹⁸ In this way, a specific activity of ~500,000 IU/mg was obtained for purified t-PA.

Cell hybridization and screening of hybridomas. Balb/c mice were immunized by subcutaneous and intraperitoneal injections of purified t-PA. P3X63-Ag.8-6.5.3. myeloma cells²⁰ were fused with spleen cells from immunized mice.²¹ After selection in HAT medium (Dulbecco's modified Eagle medium [DMEM] containing hypoxanthine, aminopterin, and thymidine),²² the supernatants were screened for specific antibody production in micro-ELISA²³ using microtiter plates coated with t-PA. The bound immunoglobulins were quantitated with horseradish peroxidase-conjugated rabbit anti-mouse IgG. Positive clones were subcloned by limiting dilution. The effect of monoclonal antibodies on the fibrinolytic activity of t-PA (final concentration 15 nmol/L) was determined by incubation of t-PA with a 40-fold molar excess of antibody for 1 hour at 37 °C followed by application of the 10- μ L aliquots of the mixture to plasminogen-containing fibrin plates.⁵ Monoclonal antibodies directed against the active site of t-PA were identified by their differential reactivity toward active t-PA or t-PA in which the active center was blocked by either diisopropylfluorophosphate (DFP) (final concentration 1 mmol/L) or D-Ile-Pro-Arg-CH₂Cl²⁴ (final concentration 10^{-5}).

The amidolytic activity of t-PA (final concentration 25 nmol/L) before and after preincubation with a 40-fold molar excess of monoclonal antibodies was measured spectrophotometrically at 405 nm using the synthetic substrate D-Ile-Pro-Arg-p-nitroanilide (S-2288) (final concentration 0.3 mmol/L).²⁵

Preparation of polyclonal antisera. Rabbit antisera against t-PA were produced by four biweekly subcutaneous injections of 50

μg of purified t-PA once in complete Freud's adjuvant and then in incomplete adjuvant. The IgG fractions were purified by affinity chromatography on protein A-Sepharose.²⁶

Blood collection and treatment of plasma samples. Venous blood samples were collected from 21 control subjects in 0.1 vol of 0.11 mol/L of citrate or in citrate containing MA-2G6 (final concentration 20 $\mu\text{g}/\text{mL}$). The samples were centrifuged at 3,000 g and 4 °C and immediately assayed or stored at -20 °C until use. Venous occlusion was performed by inflating a cuff around the upper arm, between systolic and diastolic blood pressure, for 10 minutes.

Blood samples were also obtained from 18 patients (10 men and 8 women, age 56 ± 17 years) with phlebographically confirmed deep vein thrombosis, which could not be attributed to malignancies, liver disease, infections, or a postoperative state. In three patients, the venous thrombosis was complicated by pulmonary embolism. Thirteen patients were studied between the second and fourth day after the initial diagnosis, while on heparin anticoagulation. The other five patients were studied 3 weeks after the initial diagnosis, while on oral anticoagulant therapy. Pooled fresh human plasma was depleted in t-PA by immunoadsorption on immobilized anti-t-PA monoclonal antibody (MA-62E8).¹⁴

ELISA specific for free, one-chain t-PA. The IgG fraction purified from polyclonal rabbit antiserum against t-PA was diluted in 0.04 mol/L of phosphate buffer pH 7.4, containing 0.14 mol/L NaCl, 10 g of polyethylene glycol 6,000, and 60 g saccharose per liter (coating solution).⁹ Samples (200 μL) of a 4 $\mu\text{g}/\text{mL}$ solution were incubated for 48 hours at 4 °C in the wells of polyvinylchloride microtiter plates (Costar, Cambridge, MA). The fluid was then decanted, the wells were treated for 2 hours at room temperature with 200 μL of coating solution containing 10 g/L bovine serum albumin (BSA), with 200 μL of coating solution without BSA and finally with a solution containing 10 g of mannitol and 20 g of saccharose per liter. Immediately before use, the microtiter plates were washed once with 0.04 mol/L of phosphate buffer pH 7.4, containing 0.14 mol/L of NaCl (PBS). Plasma samples collected in the presence of MA-2G6 (final concentration 20 $\mu\text{g}/\text{mL}$) were diluted in PBS-Tween-BSA, and dilutions of samples to be assayed (180 μL) were incubated for 16 hours at 4 °C in a moist chamber. The wells were then emptied and washed (three cycles in a Skatron microwash, Analis, Namen, Belgium) with PBS containing 0.002% Tween 80 (PBS-Tween). Then, to quantitate the bound t-PA-antibody complexes, 180 μL of a horseradish peroxidase-conjugated rabbit anti-mouse IgG solution diluted 1:2,000 in PBS-Tween containing 2% of normal rabbit serum was added and the mixture was incubated for 1 hour at room temperature. After repeated washing (three cycles) of the plates, the peroxidase reaction was performed by addition of 180- μL aliquots of a 0.1 mol/L of citrate-0.2 mol/L of sodium PBS pH 5.0, containing 200 $\mu\text{g}/\text{mL}$ of o-phenylenediamine and 0.003% hydrogen peroxide. After 30 minutes at room temperature, the reaction was arrested with 50 μL of 4 mol/L of sulphuric acid. The absorbance was measured at 492 nm with a multiskan spectrophotometer (Titertek, Flow Laboratories, Irvine, Scotland). Standard curves for the ELISA were constructed using t-PA-depleted plasma to which purified human one-chain t-PA (final concentration 50 ng/mL) was added. To this mixture, MA-2G6 (final concentration 20 $\mu\text{g}/\text{mL}$) was added. After preincubation for 2 hours at 4 °C, the t-PA-antibody complexes were quantitated as described above.

Inhibition of t-PA by endothelial cell-derived PA-inhibitor. Human endothelial cells were prepared from umbilical cord veins, and confluent cultures were stimulated with endotoxin as described.²⁷ Growth medium and conditioned medium of these cells were gel-filtered on a $2.5 \times 80\text{-cm}$ column of Sephadex G-200 after addition of one-chain t-PA (final concentration 0.2 $\mu\text{g}/\text{mL}$). The column was equilibrated with 0.015 mol/L of phosphate, 0.3 mol/L

of NaCl, 0.05 mol/L of EDTA, pH 7.5, containing 10 KIU/mL of aprotinin and 0.01% Tween 80. The flow rate was 6 mL/h and 4-mL fractions were collected. Relative mol wt markers were human IgGs, mol wt 140,000; phosphorylase b, mol wt 98,000; and human albumin, mol wt 66,000.

ELISA for total t-PA. A two-site ELISA reacting equally well with free and complexed forms of one-chain and two-chain t-PA was performed as described earlier.¹⁴

Other techniques. Polyacrylamide gel electrophoresis (PAGE)²⁸ was performed as described elsewhere. Amino acid analysis was performed on a Beckman 119 CL amino acid analyzer after hydrolysis in 6 mol/L of HCl in vacuo at 110 °C for 20 hours.

Reagents. Urokinase (Winkase) was a gift from Dr G. Murano, Bureau of Biologics, Bethesda, MD. Aprotinin (Trasylol) from Bayer (Leverkusen, FRG), thrombin (Topostasine) from Roche (Basel, Switzerland), and bovine plasminogen-containing fibrinogen from Organon (Oss, The Netherlands) were used. CNBr-activated Sepharose and diethylaminoethanol (DEAE) Affi Gel Blue were purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). The synthetic inhibitor D-Ile-Pro-Arg-CH₂Cl was obtained by custom synthesis at UCB (Brussels). The chromogenic substrate D-Ile-Pro-Arg-p-nitroanilide was obtained from KabiVitrum (Amsterdam). Horseradish peroxidase-conjugated rabbit anti-mouse IgG was obtained from Nordic (Tilburg, The Netherlands), and o-phenylenediamine was obtained from Fluka (Buchs, Switzerland). The P3X63-Ag.8-6.5.3. myeloma cells were a gift from Dr O. Schönher (Organon).

RESULTS

Identification of anti-t-PA monoclonal antibodies. Supernatants of hybridomas resulting from fusions of P3X63-Ag.8-6.5.3. myeloma cells with spleen cells from Balb/c mice, immunized with purified t-PA, were screened for specific antibody production in a one-site micro-ELISA using t-PA-coated plates. Nine fusions yielded 36 hybridomas producing monoclonal antibodies reactive with different epitopes in the t-PA molecule as determined by the method of Stähli.²⁹ One monoclonal antibody (MA-2G6) quenched both the fibrinolytic and amidolytic activity of t-PA when added in a 40-fold molar excess. Because this antibody bound to free t-PA but not to active site-blocked t-PA, it was used to develop the assay for free t-PA. This antibody is characterized in more detail elsewhere.³⁰

ELISA specific for free t-PA. The wells of the polyvinyl microtiter plates were coated with varying concentrations (between 0.06 and 32 $\mu\text{g}/\text{mL}$) of the IgG fraction of the t-PA-specific polyclonal antiserum. Maximal binding of 80 ng of t-PA-MA-2G6 complexes occurred at concentrations >2 $\mu\text{g}/\text{mL}$ (not shown). An IgG concentration of 4 $\mu\text{g}/\text{mL}$ was subsequently used in the assay. The influence of the concentration of the horseradish peroxidase-conjugated rabbit anti-mouse IgG was studied with dilutions between 1:1,000 and 1:12,000. Maximal response was obtained in dilution of $\leq 1:4,000$. A conjugate dilution of 1:4,000 (final IgG concentration 0.8 $\mu\text{g}/\text{mL}$) was selected for the assay (not shown).

One-chain t-PA was added to citrated plasma to a concentration of 100 ng/mL, and increasing concentrations of MA-2G6 dissolved in PBS-Tween-BSA (between 2 and 32 μg IgG/mL of plasma) were added. The mixtures were incubated for 2 hours at 4 °C, diluted in the same buffer, and

Fig 1. Influence of the concentration of murine monoclonal antibody MA-2G6 on the sensitivity of the assay. One-chain tissue-type plasminogen activator (t-PA) (final concentration 100 ng/mL) was preincubated in the presence of increasing concentrations of MA-2G6: 2 µg/mL (●); 4 µg/mL (▲); 8 µg/mL (■); 16 µg/mL (◆); and 32 µg/mL (▼). The samples were diluted in phosphate-buffered saline, Tween, and bovine serum albumin (PBS-Tween-BSA), and the t-PA-MA-2G6 complexes were quantified with horseradish peroxidase-conjugated rabbit antimouse IgG.

Fig 2. Influence of plasma matrix effects on the detection of tissue-type plasminogen activator (t-PA). One-chain t-PA (final concentration 50 ng/mL) was added to pooled normal human plasma dilutions: 1:1 (□); 1:2 (○); 1:4 (◆); 1:8 (▼); 1:16 (▲); 1:32 (■); and buffer (●). Murine monoclonal antibody MA-2G6 (final concentration 20 µg/mL), was then added, and dilutions of the mixtures in phosphate-buffered saline, Tween, and bovine serum albumin (PBS-Tween-BSA) (final t-PA concentration in the samples between 2.5 and 0.1 ng/mL) were used for quantitation of t-PA-antibody complexes with horseradish peroxidase-conjugated rabbit anti-mouse IgG.

Fig 3. (A) Reactivity of one-chain tissue-type plasminogen activator (t-PA) and two-chain t-PA in the assay for free t-PA. Calibration curves for the quantitation of one-chain t-PA (●) in human plasma were obtained by addition to t-PA depleted of t-PA (final concentration 50 ng/mL) and of murine monoclonal antibody MA-2G6 (final concentration 20 µg/mL). The samples were diluted in phosphate-buffered saline, Tween, and bovine serum albumin (PBS-Tween-BSA) (final concentration between 2.5 and 0.08 ng/mL). Poor cross-reactivity of two-chain t-PA (▲) was confirmed by addition of two-chain t-PA (final concentration between 5 and 0.08 ng/mL). (B) Sodium dodecyl sulfate-polyacrylamide gel electrophoresis: 5 µg of unreduced two-chain t-PA (lane 1), unreduced one-chain t-PA (lane 3), reduced two-chain t-PA (lane 4), and reduced one-chain (lane 6) were applied to 12% slab gels. Electrophoresis was performed overnight at room temperature and 60 V. The proteins were visualized with Coomassie blue. Unreduced and reduced standards with mol wt indicated on the right were applied in lanes 2 and 5.

the t-PA levels were then measured as described above. Figure 1 illustrates the influence of the concentration of monoclonal antibody on the sensitivity of the assay. An antibody concentration of 20 $\mu\text{g/mL}$ was further used in the ELISA.

Standard curves for the measurement of free t-PA in plasma were obtained by dilution of one-chain t-PA (final concentration between 50 and 2 ng/mL) in normal human plasma, in PBS-Tween-BSA, or in mixtures of both. Figure 2 indicates that at low dilution plasma interfered with the assay, whereas this effect was completely eliminated by 16-fold dilution. Therefore, plasma samples were diluted at least 20-fold for the assay of free t-PA. Using the assay conditions described above, between 2 and 40 ng of one-chain t-PA per milliliter of plasma could be adequately measured after 1:20 dilution (Fig 3). Thus, the sensitivity of the assay is 2 ng/mL in undiluted human plasma. Figure 3 further illustrates a large difference in sensitivity of the ELISA for one-chain as compared with two-chain t-PA. Concentrations of 100 ng/mL of two-chain t-PA in the incubation mixture had a reactivity comparable to that of 2 ng of one-chain t-PA.

The reproducibility of the assay was assessed using plasma samples containing 10, 5, and 2.5 ng of one-chain t-PA per milliliter, respectively. The within-assay coefficients of variation were $\sim 3.5\%$ ($n = 20$). The between-assay coefficients of variation ($n = 20$) were 3.0%, 6.5%, and 12.5% for plasma samples containing 10, 5, and 2.5 ng of one-chain t-PA per milliliter, respectively.

The specificity of the assay for free one-chain t-PA was established in the following way. One-chain t-PA, in which the active site was blocked with DFP or with D-Ile-Pro-Arg-CH₂Cl, was not detected in the assay at concentrations of 100 ng/mL. Following gel filtration of unconditioned growth medium used for endothelial cell culture to which 0.2 $\mu\text{g/mL}$ of one-chain t-PA was added, only one peak of immunoreactive material, eluting with an apparent mol wt of 70,000, was detected in both the ELISA for total t-PA and the ELISA based on MA-2G6 (Fig 4A). Following gel filtration of conditioned medium of human endothelial cells stimulated with endotoxin, after addition of 0.2 $\mu\text{g/mL}$ of one-chain t-PA, two peaks of immunoreactive material, corresponding to the elution position of mol wt 110,000 and 70,000, were detected in the ELISA specific for total t-PA. In the ELISA based on MA-2G6, only the material in the mol wt 70,000 position was quantitatively measured (Fig 4B).

In plasma samples of healthy individuals ($n = 21$), taken at rest, the concentration of total t-PA was 4.5 ± 1.3 ng/mL (mean $\pm$ SD) (range 2.1 to 6.9 ng/mL). Detectable levels of free t-PA were found in plasma of only 6 of these 21 healthy subjects (4.5 ± 0.8 ng/mL for free t-PA as compared with 4.9 ± 1.1 ng/mL for total t-PA). After venous occlusion ($n = 21$) measurable plasma concentrations of free t-PA were found in 18 subjects (14 ± 7 ng/mL range 4 to 32 ng/mL). The correlation coefficient (r) between total t-PA and free t-PA determined by linear regression was .92 ($n = 18$) (Fig 5). The slope of the regression line was 1.08, indicating that most of the t-PA antigen following venous occlusion occurred as free one-chain t-PA.

Fig 4. Gel filtration of mixtures of 1.0 μg of tissue-type plasminogen activator (t-PA) and 5 mL of unconditioned (A) or 5 mL of endothelial cell-conditioned medium after stimulation with endotoxin (B). Gel filtration was performed on a 2.5×80 -cm column of Sepharose G-200 equilibrated with 0.01 mol/L of phosphate, 0.3 mol/L of NaCl, 0.005 mol/L of EDTA, pH 7.5, containing 10 KIU/mL of aprotinin and 0.01% Tween 80; 3-mL fractions were collected. Absorbance at 280 nm (▲); total t-PA antigen (ng/mL) (●); free t-PA antigen (ng/mL) (■) measured after addition of murine monoclonal antibody MA-2G6 to the column fractions.

In plasma samples obtained from 18 patients with phlebographically confirmed deep vein thrombosis, the total t-PA antigen concentration was 9.1 ± 2.6 ng/mL (range 5.9 to 12 ng/mL). No free t-PA was detected in any of these samples. After venous occlusion, the total t-PA concentration increased in 16 out of 18 patients to 25 ± 11 ng/mL (range 10 to 51 ng/mL). Free t-PA was detectable in 7 of the 18 patients and increased to 9.1 ± 5.1 ng/mL (range 5.2 to 20 ng/mL) and remained < 2 ng/mL in the 11 other samples (Fig 5).

Following gel filtration of a pool of these 11 samples as described above, only one peak of immunoreactive material corresponding to the elution position of mol wt 110,000 was detected in the ELISA specific for total t-PA.

DISCUSSION

Of 36 t-PA-specific murine monoclonal antibodies, one (MA-2G6), directed against an epitope that overlaps the

Fig 5. Correlation between total tissue-type plasminogen activator (t-PA) antigen levels and free t-PA antigen levels in plasma after venous occlusion. Control subjects ($n = 21$) (●); patients with deep vein thrombosis ($n = 18$) (■).

active site of t-PA, quenched both the fibrinolytic and amidolytic activity of t-PA. Because this antibody does not react with t-PA, in which the active site is blocked with either the synthetic inhibitor D-Ile-Pro-Arg-CH₂Cl or with the fast-acting PA-inhibitor of endothelial cell origin, MA-2G6 proved useful for the specific measurement of free t-PA with an ELISA. t-PA in concentrations between 2 and 40 ng/mL could be measured adequately after 20-fold dilution of the sample, with between-assay variation coefficients ranging from 3.0 to 12.0%. Conversion of one-chain t-PA into

two-chain t-PA by cleavage of the Arg 275-Ile 276 peptide bond resulted in a 50-fold reduced reactivity of t-PA with MA-2G6.

The ELISA was further used to investigate the release and inhibition of one-chain t-PA in both healthy subjects and patients with phlebographically confirmed deep vein thrombosis. Baseline free t-PA levels could only be measured in 6 of 21 healthy subjects. Venous occlusion, however, resulted in a measurable increase of free t-PA in 18 of the 21 control subjects. A linear correlation between free t-PA and total t-PA was observed, with a slope of the regression line of 1.08. This indicates that t-PA is released from the vessel wall in its one-chain form and that at least in healthy subjects it is not rapidly converted to the two-chain form or quickly neutralized. In a pilot study, the ELISA was used to investigate the release and inhibition of t-PA after venous occlusion in patients with deep vein thrombosis ($n = 18$). Although a normal increase of total t-PA was observed in 16 of these patients, the fraction that was measurable as free t-PA was significantly lower than in control subjects and was undetectable in 11 patients. This observation is compatible with the interpretation that rapid inhibition of the released t-PA occurs in blood and is in agreement with previous results.⁴

We conclude that the present ELISA is specific for free, one-chain t-PA and is sensitive enough for the measurement of free t-PA in plasma. It may be a valuable tool for the investigation of the dynamics of t-PA release and inhibition under physiological, pharmacological, and pathological circumstances. It may also be useful to monitor thrombolytic therapy with one-chain t-PA.

Megakaryocytopoiesis: Incorporation of Tritiated Thymidine by Small Acetylcholinesterase-Positive Cells in Murine Bone Marrow During Antibody-Induced Thrombocytopenia

By Karen M. Young and Leon Weiss

The ability of small acetylcholinesterase-positive (SACHE) cells to incorporate tritiated thymidine (^3H -TdR) was studied in the bone marrow of mice made acutely thrombocytopenic by injection of guinea pig antmouse platelet serum (APS) and in control mice injected with normal guinea pig serum (NS). ^3H -TdR was administered in vivo, and bone marrow was collected at various time points thereafter. The initial labeling index (LI) for both groups was about 30%. After four hours, the LI increased and reached peak values at 48 hours, but was lower in thrombocytopenic animals. The lower peak LI in APS-treated animals may be the result of both a faster rate of influx of unlabeled cells into the acetylcholinesterase (AChE) positive cell compart-

ment and efflux of more heavily labeled, and probably polyploid, SACHE cells into the compartment of recognizable megakaryocytes. In both groups the increasing LI occurred concomitantly with a decreasing mean grain count. This may indicate cellular division by some fraction of SACHE cells. Heterogeneity in nuclear morphology was also demonstrated, and the frequency of individual morphologies was altered in APS-treated animals. In addition, cells that incorporated ^3H -TdR were larger than those that did not. This group of small cells appears to represent a pivotal point in megakaryocytopoiesis in which the switch from mitosis to endomitosis is occurring.

© 1987 by Grune & Stratton, Inc.

IN THE PATHWAY of megakaryocyte differentiation, a group of cells intermediate between the colony forming unit-megakaryocyte (CFU-M) and morphologically recognizable megakaryocytes has recently been detected. In certain species, including the mouse, these cells contain acetylcholinesterase, a cytochemical marker highly selective for megakaryocytes.^{1,2} A proportionate increase in the number of small acetylcholinesterase-positive (SACHE) cells among all acetylcholinesterase-positive cells in bone marrow occurs in response to antibody-induced thrombocytopenia²⁻⁴ and after administration of a thrombopoiesis-stimulating factor,³ and suppression of SACHE cells follows transfusion-induced thrombocytosis.⁵ The early response of these cells indicates that the first detectable response to changes in platelet mass may occur at this level.

SACHE cells appear to play a pivotal role in megakaryocytopoiesis with regard to cellular proliferation/endomitosis and feedback control by platelets, making critical an elucidation of their role in the dynamics of megakaryocytopoiesis. Few recognizable megakaryocytes initially incorporate tritiated thymidine (^3H -TdR), but by 72 hours, greater than 90% of these cells are labeled,^{6,7} even when reutilization of ^3H -TdR is minimized.⁸ Since recognizable megakaryocytes do not divide,^{9,10} we hypothesized that SACHE cells, precursors to recognizable megakaryocytes, would have an initially high labeling index (LI) and that their maturation would result in the subsequent rise in the LI of recognizable megakaryocytes. In addition, we hypothesized that the kinetics would be different in thrombocytopenic animals, since thrombocytopenia has been shown to result in a more rapid

rise in the labeling index of recognizable megakaryocytes^{11,12} and in an increase in the fraction of CFU-M in cycle.^{13,14}

Our studies on the incorporation of ^3H -TdR by SACHE cells indicate a heterogeneity with respect to cell cycle status and suggest that thrombocytopenia results in a more rapid rate of influx of cells from a precursor compartment and/or efflux of SACHE cells into the compartment of recognizable megakaryocytes. In addition we provide information on the morphology of SACHE cells that incorporate ^3H -TdR.

MATERIALS AND METHODS

Mice. BDF₁ mice (Jackson Laboratories, Bar Harbor, ME), 2 to 4 months old, were used in these studies. The animals were maintained under conventional conditions.

Antiplatelet serum. Antiplatelet serum (APS) was the generous gift of Dr Shirley Ebbe (Lawrence Berkeley Laboratory, University of California, Berkeley) and was prepared in the following manner: mouse platelets mixed with 0.15 mol/L sodium chloride (isotonic saline) and equal volumes of complete Freund's adjuvant were injected into guinea pigs. The first injection was given in the foot pad and subcutaneously (SC), and three subsequent injections were given SC only. The injections were administered over a period of one month. One week following the last injection, serum was collected from the guinea pigs and heat-inactivated at 56 °C for 30 minutes. The serum was adsorbed three times with equal volumes of saline-washed mouse red cells and stored at -20 °C in aliquots of 1 mL until use. Thawed aliquots were diluted to 3 mL with isotonic saline, and each of 18 experimental mice received 0.1 mL intraperitoneally (IP). Eighteen control animals each received 0.1 mL of normal guinea pig serum (NS) IP. NS was heated to 56 °C for 30 minutes and diluted to 3 mL with isotonic saline prior to administration.

Tritiated thymidine. Tritiated thymidine (^3H -TdR) was obtained from New England Nuclear (Boston) as a sterile aqueous solution and had a specific activity of 2.0 Ci/mmol. The solution was diluted with sterile isotonic saline and injected IP at a dose of 1.1 $\mu\text{Ci/g}$ body weight four hours after injection with either APS or NS. This time point was chosen because thrombopoiesis-stimulating factor levels have been reported to be high four hours after APS administration.¹⁵

Blood counts. Blood for counts was collected from the retro-orbital sinus directly into potassium-EDTA tubes (Sarstedt, Princeton, NJ). Platelet counts were performed on a calibrated hemocytometer at a dilution of 1:100 with 1% ammonium oxalate. Red blood cell (RBC) and white blood cell (WBC) counts were performed with a Coulter electronic particle counter, Model ZBI.

Pretreatment blood counts were performed on 26 mice. Counts were repeated four hours after injection with either APS or NS. Platelet counts in APS-treated animals had to be less than 5% of control and pretreatment values in order for the animal to be included in the experiment. This degree of thrombocytopenia appears necessary to effect quantitative changes in SACHE cells.² Exchange transfusions with platelet-poor plasma have been ineffective in producing this degree of thrombocytopenia.^{16,17} No change in RBC or WBC counts occurred in either group of mice. Platelet counts were also done on APS and NS-treated mice at the time of sacrifice.

Bone marrow samples. Animals were killed by cervical dislocation at 30 minutes and at 4, 12, 24, 48, and 72 hours after administration of ^3H -TdR. Bone marrow smears were made from split femora on acid-alcohol cleaned slides with a sable brush. Smears were heat-fixed at 50 °C for five minutes and stained for acetylcholinesterase.

Acetylcholinesterase staining. Acetylcholinesterase (AChE) activity was detected using the method of Karnovsky and Roots,¹⁸ as modified by Jackson² and Long and Williams.¹⁹ Smears were incubated at 22 °C in the following medium, made freshly each day, for 6.0 to 6.5 hours: 0.5 mg/mL acetylthiocholine iodide (Sigma, St Louis), 75 mmol/L dibasic sodium phosphate (pH 6.0), 5 mmol/L sodium citrate, 3 mmol/L copper sulfate, and 0.5 mmol/L potassium ferricyanide. Slides were then gently rinsed with distilled H₂O and fixed for ten minutes in 95% ethanol. They were counterstained in Harris' hematoxylin for 30 seconds, rinsed gently in running tap H₂O, blued in saturated lithium carbonate, and rinsed a final time in H₂O. Cytochemical control smears were incubated in media lacking substrate and were negative for reaction product in all cells.

A recent study indicated that eosinophils may contain AChE when examined by phase microscopy.⁴ To examine the selectivity of the AChE marker, 100 μm sections of bone marrow fixed in 1.5% glutaraldehyde/1.25% paraformaldehyde in 0.1 mol/L cacodylate buffer were stained for AChE activity by the method of Lewis and Knight²⁰ using acetylthiocholine iodide as the substrate. Silver/silver-gold sections were examined with a EM10CA transmission electron microscope (Zeiss, West Germany).

Mapping and ^3H -TdR-labeling of small AChE-positive Cells. Counterstained smears were coverslipped and the positions of 200 to 250 SACHE cells/mouse were located on the slides. This procedure was necessary since processing the slides for autoradiography decolorizes the AChE reaction product (see below). SACHE cells were located with phase microscopy (Zeiss) under a 100 $\times$

oil-immersion objective and had to fit the following criteria: (a) a cell diameter of less than 18 μm (measured with a calibrated stage micrometer), since morphologically recognizable megakaryocytes were always greater than 18 μm ; (b) the presence of cytoplasmic AChE reaction product, which appears black and granular under phase microscopy and diffusely golden brown under bright field microscopy; and (c) a high nuclear-cytoplasmic ratio. The cell diameter and nuclear morphology of each SACHE cell was recorded. To map each cell, stage micrometer readings were noted, and the field was photographed.

After the cells for all 36 mice were mapped, the coverslips were removed from the slides, which were then cleaned in fresh xylene. The dried smears were dipped in NTB-2 film emulsion (Kodak) diluted 1:1 with distilled H₂O. After thorough drying the slides were exposed in light-tight boxes containing dessicant at 4 °C for 30 days. The slides were then developed in fresh D-19 diluted 1:1 with distilled H₂O for five minutes (with agitation every 30 seconds), rinsed in distilled H₂O for one minute, and fixed in undiluted Kodak fixer for five minutes. The entire developing procedure was carried out at 18 °C, and all slides were processed on the same day. It is this development procedure that causes decolorization of the AChE reaction product.² The slides were then rinsed in running H₂O for 15 minutes and stained with a Romanovsky stain.

Mapped SACHE cells were located on each slide using the stage micrometer readings to find the correct field and then the photograph to locate the reaction product-positive cell (now decolorized) within the field. For each SACHE cell, the number of grains over the nucleus was counted under a 100 $\times$ oil-immersion objective (Fig 1), and the nuclear morphology was recorded again.

Background counts were estimated in two ways: (a) grain counts were done for 500 cells/slide on ten slides treated identically to the experimental autoradiograms, except that the smears were made with bone marrow from mice that were not injected with ^3H -TdR; and (b) grain counts were done on the experimental autoradiograms over areas away from the cells. Background counts determined by both methods were low (mean grain count was less than one grain/cell). For a cell to be considered labeled, it had to have a grain count of at least three times the background count.

The grain count data were analyzed at each time point after administration of ^3H -TdR to calculate the LI (percentage of SACHE cells that were labeled) and the mean grain count of the labeled SACHE cells. The data were analyzed statistically using a three-way analysis of variance.

Fig 1. SACHE cells in bone marrow of a normal serum-treated mouse 30 minutes after administration of ^3H -TdR (phase contrast, original magnification 500 $\times$; current magnification 375 $\times$). (A) Note AChE reaction product in cytoplasm of SACHE cells (arrows). (B) Same field as (A) after processing for autoradiography. Note that the AChE reaction product is decolorized and that one SACHE cell with a lobulated nucleus has incorporated ^3H -TdR.

RESULTS

Platelet counts. Platelet counts are presented in Fig 2. For all experimental animals the platelet count was less than 5% of both the pretreatment and control values. Thereafter, the platelet count increased and reached pretreatment values by 76 hours after APS administration. NS had no effect on the platelet count.

Labeling index of SACHE cells. The labeling index (LI) for SACHE cells was defined as the percentage of SACHE cells that were labeled and was plotted against time after ^3H -TdR administration for experimental and control animals (Fig 3). The initial LI (at 30 minutes) for both groups was about 30% (29% for experimentals and 31% for controls). At four hours there was no change (29% for experimentals and 32% for controls), but by 12 hours the LI reached about 50% in both groups (52% in experimentals and 51% in controls). For the next three time points experimental and control values differed. At 24 hours the LI was 42% for experimental animals and 69% for controls. Both groups attained peak values at 48 hours (77% in experimentals and 92% in controls). By 72 hours there was a decline in LI for both groups (54% in experimentals and 76% in controls). The difference between experimental and control groups was significant ($P < 0.02$).

Mean grain counts. The mean grain count (MGC) for each animal was calculated by averaging the grain counts of all the labeled cells for that animal. For comparison, the MGC at 30 minutes was assigned a value of 1.0, and each subsequent MGC was expressed as a proportion of the initial value. These data are presented in Fig 4. Both groups demonstrated a rise in MGC at four hours, and the MGC decreased at each subsequent time point. The difference in MGC between groups was not significant ($P > 0.1$).

To summarize, in both experimental and control groups, the LI increased after four hours, peaked at 48 hours, and then decreased. After 12 hours the LI for the experimental group was lower than for the control group. In both groups the MGC decreased sharply at first and thereafter at a slower rate.

Morphology of SACHE cells. The nuclear morphology of SACHE cells was sometimes difficult to assess with

Fig 2. Mean platelet counts of mice after administration of antiplatelet serum (APS) or normal serum (NS). The mean platelet count of 26 untreated mice is shown on the graph for comparison. Error bars indicate ± 1 standard error of the mean (SEM). Where error bar is absent, SEM falls within the point.

certainly, as round and tightly lobulated nuclei could not always be distinguished. If the nuclear morphology could be determined unequivocally, the cell was included in the analysis. The three morphologic types described by Long and Williams¹⁹ were noted in the present study, although the percentages were slightly different. Examples of SACHE cells before and after autoradiographic processing are presented in Fig 1.

In APS-treated mice, there was an altered frequency distribution of nuclear morphologies that varied with time (Table 1). As indicated by these data, experimental mice had decreased percentages of cells with a round and indented nucleus and an increased percentage of cells with a lobulated nucleus at early time points. Later on the percentage of cells with a round or indented nucleus was increased along with a decrease in the proportion of cells with a lobulated nucleus ($P < 0.05$).

The nuclear morphology of cells initially labeled was compared to that of unlabeled cells (Table 2). The frequency distribution of nuclear morphologies of both labeled and unlabeled cells was similar to that of all SACHE cells at 30 minutes after ^3H -TdR or 4.5 hours after APS administration, indicating that uptake of ^3H -TdR was not favored by a

Fig 4. Relative mean grain count of SACHE cells in APS- and NS-treated mice. A value of 1.0 was assigned to the mean grain count (MGC) at 0.5 hour, and each subsequent MGC was expressed as a proportion of the initial value. The actual values ± 1 SEM for experimental and control animals respectively were: at 30 minutes, 22 ± 1 and 25 ± 2 ; at 4 hours, 30 ± 5 and 37 ± 5 ; at 12 hours, 18 ± 2 and 17 ± 3 ; at 24 hours, 9 ± 1 and 14 ± 1 ; at 48 hours, 8 ± 0 and 11 ± 1 ; and at 72 hours, 6 ± 0 and 8 ± 2 .

Table 1. Nuclear Morphology of SACHE Cells

Time after APS (h)	n	Round	Indented	Lobulated
4.5	976	1.35 $\pm$ 0.02	6.50 $\pm$ 0.07	92.14 $\pm$ 0.08
8	663	4.79 $\pm$ 0.08	11.65 $\pm$ 0.14	83.56 $\pm$ 0.22
16	683	3.91 $\pm$ 0.08	10.92 $\pm$ 0.13	85.17 $\pm$ 0.20
28	560	1.96 $\pm$ 0.05	12.39 $\pm$ 1.80	85.60 $\pm$ 0.08
52	664	9.27 $\pm$ 0.06	21.68 $\pm$ 0.21	69.05 $\pm$ 0.21
76	623	9.35 $\pm$ 0.06	22.58 $\pm$ 0.15	68.07 $\pm$ 0.14
Control	3,849	5.06 $\pm$ 0.03	16.81 $\pm$ 0.08	78.13 $\pm$ 0.11

Values are mean percent $\pm$ SEM; n, number of SACHE cells evaluated.

cell with a particular nuclear morphology. In APS-treated mice, the percentage of labeled cells with a round nucleus showed a greater increase with time than that of unlabeled cells. By 72 hours after ^3H -TdR administration, 12.15% $\pm$ 0.09% had a round nucleus (n = 337; mean $\pm$ SEM) as compared to 5.54% $\pm$ 0.39% (n = 286) in unlabeled cells and 9.35% $\pm$ 0.10% (n = 623) in all SACHE cells from APS-treated mice at 72 hours ($P < 0.02$).

SACHE cells were subject to both shrinkage and swelling due to the effects of fixation, histochemical reactions, and autoradiographic processing. Cell diameters could not, therefore, be considered absolute measures of cell size and were more useful for relative comparisons among groups of cells. The mean diameter of SACHE cells from APS-treated animals was 12.59 $\pm$ 0.23 μm (n = 4,609; mean $\pm$ SD) and for NS-treated animals was 12.63 $\pm$ 0.18 μm (n = 4,387; mean $\pm$ SD). There were no significant differences between time points or treatment groups ($P > 0.1$). In APS-treated mice the cell diameter of initially labeled cells was significantly greater than that of unlabeled cells (14.24 $\pm$ 1.69 μm and 11.96 $\pm$ 1.59 μm , respectively; $P < 0.001$). Results from control animals were similar.

Electron microscopy. The AChE reaction product was present in mature megakaryocytes and in a population of small cells but was absent in eosinophils at all stages of maturation (Fig 5).

DISCUSSION

The following conclusions can be made from the present study: (a) SACHE cells are heterogeneous with respect to cell cycle, with only 30% initially incorporating ^3H -TdR. The percentage increases with time, peaking at 48 hours, but is lower in APS-treated animals after 12 hours. The MGC decreases concomitantly with the increasing LI. (b) SACHE cells are heterogeneous with respect to nuclear morphology, and the lobulated nucleus is the most prevalent form, followed by the indented and round forms. Following injection of APS, the percentages of round and indented forms

Fig 5. Electron micrograph of bone marrow stained for AChE activity (original magnification 7200 $\times$; current magnification 5400 $\times$). An AChE-positive cell contains reaction product in the nuclear envelope and in profiles of endoplasmic reticulum (arrows). An eosinophil with characteristic crystalloid inclusions (arrow heads) contains no reaction product.

decrease below control values but are higher than control values after two days. Cells with all three nuclear morphologies are capable of incorporating ^3H -TdR, and the percentage of cells with a round nucleus is greater in labeled than in unlabeled cells by 72 hours. (c) While the size of cells in the compartment of SACHE cells remains stable, cells that initially incorporate ^3H -TdR are larger than unlabeled cells.

We had hypothesized that a high proportion of SACHE cells would incorporate ^3H -TdR based on the increased LI of mature megakaryocytes by 24 hours^{6,7,21} and the apparent susceptibility of precursors of mature megakaryocytes to cytotoxic drugs.^{22,23} Since only 30% of SACHE cells initially labeled in this study, the possibility that mature megakaryocytes have a more immediate precursor than the SACHE cell was considered. This is unlikely in view of the studies on density profiles²⁴ and the relationship of SACHE cells to megakaryocytes.²⁵ A more likely explanation for the initially low labeling index is that SACHE cells are heterogeneous with respect to cell cycle status.

The lower peak LI in thrombocytopenic animals is probably the result of both an influx of cells from an initially unlabeled compartment and an efflux of labeled cells into the compartment of recognizable megakaryocytes, with both of these events occurring at a more rapid rate in thrombocytopenic animals. Under conditions of acute thrombocytopenia similar to those in the present experiments, the increase in

Table 2. Nuclear Morphology of Labeled and Unlabeled SACHE Cells 30 Minutes Post- ^3H -TdR Administration

	Labeled				Unlabeled			
	n	Round	Indented	Lobulated	n	Round	Indented	Lobulated
APS-treated	275	1.58 $\pm$ 0.08	5.26 $\pm$ 0.23	93.17 $\pm$ 0.22	701	1.31 $\pm$ 0.02	6.98 $\pm$ 0.10	91.72 $\pm$ 0.09
NS-treated	252	4.09 $\pm$ 0.17	14.39 $\pm$ 0.80	81.53 $\pm$ 0.76	683	3.45 $\pm$ 0.13	11.49 $\pm$ 0.14	85.06 $\pm$ 0.24

Values are mean percent $\pm$ SEM; n, number of SACHE cells evaluated.

CFU-M in S phase occurred by 24 hours and reached a maximum value of 49% at 40 hours.¹⁴ While a slight increase occurred at 12 hours, no change was observed at six hours. Thus, the majority of CFU-M would be unlabeled by ³H-TdR administered four hours after APS. As these unlabeled cells begin to synthesize DNA, they would eventually acquire the AChE marker and would enter the SACHE cell compartment. These unlabeled cells would decrease the LI. In control animals, influx of unlabeled cells may also occur, but at a slower rate. Efflux of labeled SACHE cells into the compartment of recognizable megakaryocytes is also likely to occur at a more rapid rate in thrombocytopenic animals, as labeled cells appear in the compartment of Stage I megakaryocytes more rapidly in thrombocytopenic animals.^{11,12}

Antibody-induced damage of SACHE cells is an unlikely cause for the lower peak LI in experimental animals. Previous studies have suggested that damage to mature megakaryocytes is minimal or lacking when small single doses of antiserum are used.^{16,17,26-28} In addition, administration of thrombopoietin or APS had similar effects on SACHE cells with respect to changes in the percentage of these cells in the bone marrow.³ Also, no reduction in CFU-M occurred when bone marrow cells were preincubated with APS prior to plating or when APS was included in the plating mixture.¹⁴

The decrease in LI at 72 hours in both groups of mice can be explained by the maturation of labeled SACHE cells into recognizable megakaryocytes and the entry of unlabeled cells into the SACHE cell compartment by 72 hours. This is consistent with reports that recognizable megakaryocytes attain peak labeling at three days due to an influx of labeled precursors and maturation of cells through the compartment.^{6,7}

In both experimental and control groups in this study, the MGC decreased while the LI increased. Cellular division, resulting in the distribution of labeled DNA among an increased number of cells, is one explanation for this phenomenon. However, while some SACHE cells may be capable of cellular division, most are not proliferating^{25,29} but are undergoing endomitosis. Other factors that may have contributed to the concurrent increasing LI and decreasing MGC are efflux of more heavily labeled SACHE cells into the compartment of recognizable megakaryocytes and influx of lightly labeled cells from the CFU-M compartment. Further studies are needed to explore these various possibilities.

Consistent with a previous report,¹⁹ we found that the most frequent nuclear morphology is the lobulated form. If this is also the most mature SACHE cell, the higher percentage present four to 24 hours after APS may represent a "shift to the right" in this population of cells. This is also suggested by the larger size of initially labeled cells.

In an earlier study,³⁰ hydroxyurea, an inhibitor of DNA

synthesis that lethally damages cells in S phase,³¹ was found to reduce only SACHE cells with a round nucleus, which represented less than 2% of the total SACHE cell compartment.¹⁹ Our studies indicate that uptake of ³H-TdR, which labels cells in DNA synthesis but is not cytotoxic at the doses used,³² is not limited to cells with a round nucleus. In fact, the highest percentage of cells that initially label have a lobulated nucleus. The marked difference in the mechanisms of action of these agents makes comparison difficult; however, the discrepancy in the percentage and morphology of cells affected may be the result of a higher resistance of polyploid SACHE cells, which incorporate ³H-TdR during endomitosis, to the lethal effects of hydroxyurea.

Recently a question was raised about the positive staining of eosinophils at the light microscopic level.⁴ In the present study it is unlikely that the AChE-positive cells represent eosinophils for the following reasons: (a) eosinophils that have a lobulated or segmented nucleus are postmitotic and therefore would not incorporate ³H-TdR; (b) cytoplasmic reaction product was visualized as black and granular with phase microscopy and diffusely golden brown (Hatchett's brown) under bright field microscopy; after decolorization of the AChE reaction product, no eosinophilic granules were seen in the Romanovsky-stained smears; and (c) in the examination of marrow sections by electron microscopy, we found that with the more sensitive technique of ultrastructural localization of AChE reaction product, positive eosinophils were never found at any stage of maturation.

These data are consistent with the following model of megakaryocytopoiesis: the CFU-M, normally in a relatively quiescent state, replenishes its own pool while feeding the SACHE cell compartment. SACHE cells are a heterogeneous population of cells with respect to cell cycle status and morphology, and are immediately responsive to marked changes in platelet mass. At least some proportion of SACHE cells are capable of cellular proliferation, while the most mature have begun the process of endomitosis. This compartment of cells is replenished by the CFU-M, and this occurs at a more rapid rate after the stress of thrombocytopenia. In turn, SACHE cells feed the compartment of recognizable megakaryocytes as the most mature SACHE cells, which are larger and have a lobulated nucleus, become Stage I megakaryocytes. Differentiation of cells committed to megakaryocytopoiesis may be directed by local and systemic mechanisms. SACHE cells constitute a heterogeneous group of cells in which the key element of differentiation is the change from mitosis to endomitosis, regulated at least in part by the end product of mature megakaryocytes.

ACKNOWLEDGMENT

The authors would like to thank Dr Shirley Ebbe for her generous gift of guinea pig antimouse platelet serum.

Erythroid Marrow Function in Anemic Patients

By Mario Cazzola, Pensri Pootrakul, Helmut A. Huebers, Mary Eng, Joseph Eschbach, and Clement A. Finch

Erythropoietic activity is known to be closely associated with marrow iron uptake. A modification of the standard measure of plasma iron turnover has been developed in which erythron transferrin uptake (ETU) rather than iron uptake has been calculated. The ETU has the advantage of providing a parameter of erythroid marrow activity independent of change produced by plasma iron and transferrin saturation. Measurements in 80 patients with anemia were compared to the normal value of 60 ± 12 $\mu\text{mol/L}$ whole blood/d. The mean ETU for ten patients with severe aplastic anemia and for six patients with pure red-cell aplasia were 12 ± 8 and 12 ± 11 $\mu\text{mol/L}$ whole blood/d, respectively. In ten transfusion-dependent patients with renal failure under dialysis therapy, the mean value was 35 ± 11 , while ten other dialyzed patients who were transfusion independent had a mean ETU of 73 ± 21

$\mu\text{mol/L}$ whole blood/d. Sixteen patients with hemolytic anemia had an average ETU of 400 ± 130 , while 28 patients with ineffective erythropoiesis had a mean value of 474 ± 147 $\mu\text{mol/L}$ whole blood/d. While patients with hypoproliferative anemia showed no relation between the severity of anemia and ETU, those with hyperproliferative erythroid marrow showed increasing values as the anemia became more severe. Sequential measurements in patients with aplastic anemia under treatment and in thalassemic patients under transfusion therapy showed the value of this measurement in monitoring the effects of treatment on erythroid marrow activity. It is concluded that the measurement of ETU provides a more direct ferrokinetic evaluation of erythroid activity in anemic states.

DISORDERS of erythroid marrow function may be characterized as affecting marrow proliferation and/or red cell maturation. For clinical purposes the former is evaluated by marrow aspiration or biopsy, and the latter by the relationship between the reticulocyte index and marrow proliferation as judged by marrow examination.¹ Limitations to the quantitation of erythroid marrow activity from a minute sample have led to a continued search for a more adequate means of estimating erythroid marrow activity. Beginning with the original measurements of Huff and associates,² the measurement of plasma iron turnover has been continually refined to reflect more quantitatively erythron iron uptake.³⁻⁷

In the last few years, attention has focused on the reaction between transferrin iron and its membrane receptors.^{8,9} The assumption of a single plasma iron pool, so essential to previous kinetic measurements, has been shown to be erroneous.¹⁰ There are actually two plasma iron pools, one composed of monoferric transferrin and the other of diferric

transferrin. The diferric molecule has a greater capacity to deliver iron to tissue receptors than the monoferric species.^{9,11} Since the in vivo loading of iron on transferrin is a random phenomenon, the quantitative relationship between these two plasma iron pools and their respective iron clearance is predictable.¹⁰⁻¹² The critical reaction is the uptake of the transferrin-iron-receptor complex into the cell, and this occurs at the same rate, regardless of whether there are one or two molecules of iron on the transferrin molecule. In a recent study dealing with normal subjects, a simple approach to the measurement of transferrin-receptor interaction in normal man was presented, and the transferrin uptake was shown to be independent of plasma iron concentration and transferrin saturation.¹³ This approach has now been extended to the measurement of the erythron transferrin uptake in anemic patients.

MATERIALS AND METHODS

Patients. Ferrokinetic studies were performed in a total of 80 patients selected to provide extremes in erythropoiesis. A first group included ten individuals with severe aplastic anemia (AA) and six with pure red-cell aplasia (PRCA). Criteria for the diagnosis of severe aplastic anemia¹⁴ included a hypocellular bone marrow on bone marrow biopsy (less than 30% cellularity) and two of the following three factors: reticulocyte index <1 , granulocytes $<0.5 \times 10^9/\text{L}$, and platelets $<20 \times 10^9/\text{L}$.¹⁴ Criteria for the diagnosis of PRCA¹⁵ included the virtual absence of erythroid cells in the marrow but abundant marrow precursors for other cell species, a transfusion-dependent anemia associated with a decrease in reticulocyte index below 1, the presence of circulating granulocytes $>2 \times 10^9/\text{L}$, and platelets $>100 \times 10^9/\text{L}$. In addition to the above criteria and in order to select the most severely affected individuals, only those with less than or equal to 10% of injected radioiron in circulating red cells at two weeks were included in this first group. A second group was composed of 20 patients with severe renal disease with azotemia, all of whom were on renal dialysis. Within this group ten patients needed repeated transfusions to maintain their hematocrit over 20%, and ten other patients did not require transfusion.

The remaining 44 patients had anemia associated with erythroid marrow hyperplasia. There were 16 patients with hemolytic anemia, eight of whom had sickle cell disease, four hereditary spherocytosis, two red cell enzyme defects (pyruvate kinase deficiency, glucose 6-phosphate isomerase deficiency), one autoimmune hemolytic ane-

mia, and one fragmentation hemolysis. Another group of 28 patients demonstrated ineffective erythropoiesis with erythroid marrow hyperplasia. Ten of these patients had β -thalassemia intermedia with hemoglobin concentrations between 6 and 9 g/dL,¹⁶ while 16 patients had β -thalassemia/Hemoglobin E disease, the criteria for which have been described elsewhere.¹⁷

Ferroketic measurements. Details of the measurement of plasma iron turnover have been previously summarized.^{18,19} In these studies it was standard practice to inject $^{59}\text{FeSO}_4$ (0.2 μg containing 2 μCi ^{59}Fe at pH 2) intravenously (IV) over a period of five minutes. However, in individuals with transferrin saturation >70%, radioiron was bound to normal plasma in vitro, and then the tracer saturation was adjusted to that of the patient's own plasma using cold ferrous ammonium sulfate.¹³

Plasma iron turnover was routinely calculated employing the formula¹⁹:

$$\text{PIT (mg/dL whole blood/d)} = \frac{\text{PI } (\mu\text{g/dL}) \times (100 - \text{Hct} \times 0.9)}{\text{T}_{1/2} \text{ (min)} \times 100}$$

This formula is suitable for turnover measurements as long as the blood volume (BV) is not significantly different from that predicted ($\pm 10\%$). A comparison was made of the determined BV based on the dilution of the injected isotope, as compared to the predicted BV.²⁰ Where there was a significant increase (>10%), the observed PIT was corrected by multiplying it by the ratio between determined and predicted plasma volume for the patient's plasmacrit.¹⁹

In some instances the radioiron red-cell utilization (RCU) was calculated from the red cell activity at 14 days and the amount of radioactivity injected as described by Cook and Finch.¹⁹

Additional calculations, discussed more in detail elsewhere,¹³ were made to convert the plasma iron turnover to the transferrin-iron complex uptake by the erythron. This involved (a) the subtraction of the extravascular plasma flux (EVF), (b) a correction designed to convert tissue iron uptake (IU) to tissue transferrin uptake (TU), and (c) the subtraction of nonerythroid transferrin uptake to leave erythron transferrin uptake (ETU).

$$\text{EVF (mg/dL wb/d)} = \text{PI } (\mu\text{g/dL}) \times \frac{(100 - \text{Hct} \times 0.9)}{100} \times 0.0015$$

$$\text{IU (mg/dL wb/d)} = \text{PIT} - \text{EVF}$$

$$\text{TU } (\mu\text{mol/L wb/d}) = \frac{\text{IU (mg/dL wb/d)} \times 10,000}{56} \times \frac{200 + 2.2S}{200 + 6.4S}$$

where S is the percent transferrin saturation, and wb/d stands for whole blood/day.

The final correction to allow for transferrin-iron going to non-erythroid receptors is made by subtracting the mean volume value of 11 $\mu\text{mol/L}$ whole blood/day¹³ from the calculated transferrin uptake:

$$\text{ETU } (\mu\text{mol/L wb/d}) = \text{TU } (\mu\text{mol/L wb/d}) - 11$$

Plasma iron and transferrin saturation were measured as described elsewhere.^{21,22} Hematocrit was determined by the micro-method. ^{59}Fe activity was determined by gamma counting. Plasma volume was calculated from the ^{59}Fe -transferrin dilution.¹⁹

Statistical analysis. Statistical analysis was performed using the CLINFO computer system (University of Washington, Seattle, WA). All results are given as mean $\pm$ 1 SD. The significance of the differences between means was tested by the Student's *t* test.

RESULTS

Data obtained in 80 subjects are summarized in Table 1. Ten patients with aplastic anemia had an average transferrin

saturation of $90\% \pm 9\%$, a mean plasma iron turnover of 0.57 ± 0.10 mg/dL whole blood/d, and a mean ETU of 12 ± 8 $\mu\text{mol/L}$ whole blood/d. Radioactivity in the blood at two weeks amounted to an average of $4\% \pm 4\%$ (range 0% to 10%). Six additional patients with PRCA had a mean transferrin saturation of $94\% \pm 5\%$, a mean plasma iron turnover of 0.57 ± 0.15 mg/dL whole blood/d, an ETU of 12 ± 11 $\mu\text{mol/L}$ whole blood/d, and a mean red-cell utilization at two weeks of $3\% \pm 3\%$ (range 0% to 6%). Thus, in these subjects the mean values for PIT were 80% of normal whereas ETU values averaged 20% of normal.

Ten patients with transfusion-dependent renal failure under continuous dialysis treatment had a mean transferrin saturation of $80\% \pm 15\%$, a mean plasma iron turnover of 0.73 ± 0.16 mg/dL whole blood/d, and an average ETU of 35 ± 11 $\mu\text{mol/L}$ whole blood/d. Red cell utilization in the ten patients averaged $26\% \pm 10\%$ (range 12% to 47%). By contrast, a second group of dialyzed patients who were able to sustain their hematocrit without transfusion had a mean transferrin saturation of $28\% \pm 6\%$, a mean PIT of $0.77\% \pm 18\%$ mg/dL whole blood/d, and a mean ETU of 73 ± 21 $\mu\text{mol/L}$ whole blood/d. Their red cell utilization averaged $71\% \pm 13\%$ (range 55% to 89%). Whereas there was no difference between the mean PITs of the two groups of renal patients ($t = 0.55$, $P > 0.05$), the mean ETU of those patients who did not need blood transfusions was significantly higher than that of transfusion-dependent patients ($t = 5.17$, $P < 0.0001$).

Sixteen patients with hemolytic anemia were heterogeneous in respect to the cause of their anemia, to its degree (hematocrit varied from 18% to 35.5%), plasma iron concentration (46 to 279 $\mu\text{g/dL}$), and transferrin saturation (11% to 91%). Plasma iron turnover averaged 3.86 ± 1.45 mg/dL whole blood/d but ranged from 1.26 to 6.64 mg/dL whole blood/d. ETU averaged 400 ± 130 $\mu\text{mol/L}$ whole blood/d but ranged from 168 to 612 $\mu\text{mol/L}$ whole blood/d.

A similar heterogeneity was observed in 28 patients with ineffective erythropoiesis. Hematocrits varied from 15.1% to 34.5%, plasma iron from 52 to 308 $\mu\text{g/dL}$, and transferrin saturation from 16% to 98%. Mean PIT was 5.11 ± 1.85 mg/dL whole blood/d with a range from 1.40 to 9.23, and ETU values averaged 474 ± 147 $\mu\text{mol/L}$ whole blood/d with a range from 176 to 809.

All patients with aplastic anemia, pure red-cell aplasia, and renal failure associated with anemia had erythroid marrow activity as judged by ETU between 0 and $1.6 \times$ basal. On the other hand, patients with hemolytic anemia and ineffective erythropoiesis showed values between 2.8 and 13.5 times basal (all values but two being greater than 3). When ETU was plotted against the hematocrit (Fig 1), there was no apparent relationship among hypoproliferative patients between the severity of the anemia and ETU ($r = 0.32$, $P = 0.06$), whereas there was an inverse correlation among hyperproliferative patients ($r = -0.71$, $P < 0.001$).

Sequential studies were carried out in five patients with pure red-cell aplasia under treatment after an appropriate interval of time (Fig 2). These measurements showed no change in marrow activity in two patients and improvement in three by both improvement in hematocrit and clearly

demonstrable increases in marrow erythroid activity. Sequential measurements in patients with thalassemia or sickle cell anemia undergoing transfusion therapy showed the suppressive effect of higher hematocrit on erythroid activity but erythropoietic activity was still two to three times basal for hematocrit values around 40% (Fig 3). In these latter studies there was a close correlation ($r = 0.86$, $P <$

0.01) between ETU and erythroid: myeloid ratio of the marrow.

DISCUSSION

Within the circulating blood there is a constant flow of iron from donating cells via transferrin to membrane transferrin receptors of tissues requiring iron. The marrow normally receives about four fifths of all iron passing through

Fig 1. Relationship between hematocrit and erythron transferrin uptake (ETU) in anemic patients. Patients with conditions known to be associated with impaired proliferative response to anemia are shown with open circles (○) and patients with conditions associated with a normal proliferative response to anemia are shown with solid circles (●).

Fig 2. Ferrokinetic studies carried out before and after treatment in patients with pure red cell aplasia. Three patients showed both improvement in hematocrit and increased marrow erythroid activity, while two unresponsive patients showed no change in either.

Fig 3. Sequential ferrokinetic studies in patients with thalassemia and sickle cell anemia undergoing transfusion therapy. The relationship between hematocrit concentration and erythropoietic activity is illustrated.

the plasma for incorporation into hemoglobin. It has therefore been assumed that erythroid marrow function would be quantitatively related to iron turnover. In some conditions, however, the plasma iron turnover gives a poor reflection of the state of erythropoiesis, since other pathways of iron exchange are increased while erythron iron uptake is reduced. A number of elegant models of iron kinetics have been developed that take into consideration the amount of iron going to erythroid and nonerythroid tissues and various refluxes of iron from those tissues.^{4,6,7} Such models require sophisticated processing of experimental data derived from blood sampling over ten to 14 days, and although they have been of value in developing an understanding of erythroid disorders, they are not practical for clinical usage and the results are themselves subject to criticism. These models are based on the erroneous assumption of a single plasma iron pool and, for the most part, have not considered the effect of transferrin saturation on iron turnover. The principal focus of this work was to develop a simple ferrokinetic approach to quantitation of erythropoiesis by applying recent knowledge concerning iron exchange between transferrin and body cells to ferrokinetic measurements.

The plasma iron turnover is derived from the hematocrit, the plasma iron, and the rate of disappearance of radioiron from circulation.^{18,19} Before a relationship between iron turnover and erythropoietic activity could be exploited, it was first necessary to allow for transferrin iron going to extravascular fluid and not initially taken up by cells. This was done based on the relationship previously described by Cook et al between plasma iron and extravascular flux.⁴

The key to the present approach depends on the reaction between transferrin iron and its membrane receptors. We have previously shown that the plasma iron turnover increases with increasing plasma iron and transferrin saturation.¹³ Cook et al⁴ thought this was due to increased nonerythroid iron uptake, an assumption no longer tenable. It is now known to be due to an increased proportion of diferric iron as

saturation increases and the greater capacity of diferric transferrin to deliver iron to all membrane receptors, erythroid and nonerythroid. This does not necessarily imply that erythropoiesis is increased at higher saturations but is rather a reflection of the increased proportion of diferric transferrin molecules.

We have demonstrated that transferrin uptake can be derived empirically from plasma iron turnover, once extravascular flux has been subtracted, knowing the preference ratio between the two forms of plasma iron and the relative amount of each.¹³ Transferrin uptake so derived was found to be independent of plasma iron and transferrin saturation, and this suggested that the critical measurement of erythroid marrow function could be best described by erythroid transferrin uptake once allowance had been made for nonerythroid transferrin uptake. The nonerythroid tissues of the body have a limited capacity to assimilate iron. After injection of radioiron, normal subjects have only about 15% of the activity outside of the red cell mass at two weeks. Furthermore, there is little evidence to date that these nonerythroid receptors, most of which reside in the liver, can change greatly in number except in the presence of iron deficiency (Tanin et al, unpublished data). This means that the number of iron-bearing transferrin molecules reacting with membrane receptors on nonerythroid tissues can be considered relatively constant, and the mean normal value of 11 μmol transferrin/L whole blood/d has been assumed in the present study.¹³ According to these calculations, erythron transferrin uptake in normal subjects averages 60 ± 13 μmol /L whole blood/d.

A first opportunity to examine the appropriateness of the various corrections made to obtain the ETU was provided by patients with severe aplastic anemia and pure red-cell aplasia. Among the 16 patients studied, whose plasma iron turnover ranged from 0.38 to 0.77 mg/dL whole blood/d, values for ETU ranged from 0 to 28 μmol /L whole blood/d. No patient had a value below 0, indicating that estimates of nonerythroid iron turnover were not overcorrected. The red cell utilization of 3% to 4% when compared to the mean ETU of 12% the basal value suggested that a major portion of the residual erythroid activity in these patients did not result in the production of viable red cells. Evidence of dyspoiesis in aplastic anemia has been reported.^{23,24}

Studies in renal patients provided another opportunity to compare the clinical status with the ferrokinetic evaluation of erythropoiesis. Renal patients have a combination of impaired marrow stimulation due primarily to inadequate erythropoietin production and also increased red cell hemolysis, but erythropoiesis is effective.¹⁸ Studies of two groups of dialyzed patients, one self-sufficient and the other transfusion dependent, showed no difference in plasma iron turnover (0.77 ± 0.18 v 0.73 ± 0.16 mg/dL whole blood/d) but a conspicuous difference in erythroid activity in the two groups, ie, 73 ± 21 v 35 ± 11 μmol /L whole blood/d. Assuming that both had the same degree of shortening of red cell life span to about one-half normal, the difference in hemoglobin concentration was adequately explained by the greater impairment in production in the transfused group.

Patients with hemolytic anemia had an average ETU of 400 ± 130 , and patients with ineffective erythropoiesis $474 \pm$

147 $\mu\text{mol/L}$ whole blood/d. These can be translated into mean erythropoietic rates of 6.7 and 7.9 times basal, respectively. In some of these patients the reduction of erythropoiesis after transfusion was measured (Fig 3). Quantitative aspects of the relationship between blood hemoglobin concentration or hematocrit and suppression of erythropoiesis are not well defined. There is ample clinical evidence that suppression of erythropoiesis by transfusion is required for thalassemic patients if distension of the marrow and distortion of the skeleton are to be prevented. Previous measurements on patients with thalassemia were made by Cavill et al²⁵ at hemoglobin levels from 9 to 17 g/dL. According to their detailed analysis of the plasma iron disappearance curve, erythropoiesis as judged by marrow iron turnover became normal or subnormal at a blood hemoglobin concentration of 11 to 12 g/dL. They comment, however, that the marrow still showed normoblastic hyperplasia. It might be anticipated from the type of analysis performed by them that ineffective erythropoiesis could not be completely separated from iron exchange with nonerythroid tissues, and this could cause total erythropoiesis to be underestimated.^{18,26} In studies reported here, erythropoiesis did decrease as the hemoglobin concentration was increased by transfusion but remained

two to three times basal at a hemoglobin concentration of 11 to 12 g/dL, and parallel changes in erythroid: myeloid ratio validated the ferrokinetic measurement. Evaluation of erythroid activity can be of value in determining the degree of erythroid suppression after transfusion in individual patients with thalassemia major and also in deciding whether patients with thalassemia intermedia should be transfused.

Taken as a group, individuals with an impaired marrow response to anemia, ie, less than two times basal, showed no relationship between the ETU and hematocrit, the slope of the regression line being not significantly different from 0. This suggested that the impairment in production was the dominant feature in causing the anemia and that the erythroid marrow could not respond appropriately to the erythropoietin stimulus produced by anemia. In contrast, patients with an appropriate proliferation response to anemia showed an inverse relationship between hemoglobin concentration and erythropoietic response. This would be consistent with an increased marrow stimulation by erythropoietin as the hemoglobin fell.¹ A similar relationship has been observed employing a more complex ferrokinetic approach.²⁷

cis-Retinoic Acid Stimulates the Clonal Growth of Some Myeloid Leukemia Cells In Vitro

By H. Jeffrey Lawrence, Kevin Conner, Michael A. Kelly, Mark R. Haussler, Paul Wallace, and Grover C. Bagby, Jr

We studied the effects of cis-retinoic acid (cisRA) on the clonogenic growth of samples of leukemic cells from 35 patients with acute nonlymphocytic leukemia (ANLL). We observed significant inhibition of leukemic colony growth in 17 samples by 10^{-7} to 10^{-6} M cisRA. However, we found that retinoid exposure resulted in striking stimulation of clonal growth in ten samples at the same drug concentrations. With the exception of cases with promyelocytic features, there was no morphologic or functional evidence that cisRA induced the leukemic blasts to differentiate. Both inhibition and stimulation were dose-dependent and observable at pharmacologically achievable levels of cisRA. Leukemic cells with monocytic features more frequently demonstrated a stimulatory response than did those without monocytic features. Depletion of T lymphocytes and monocytes did not alter the type of growth response.

THERE HAS BEEN substantial interest in the use of retinoids in the chemoprevention of cancer and as noncytotoxic chemotherapeutic agents in malignancy. Numerous studies in animal models have demonstrated the capacity of vitamin A and its derivatives to prevent malignant progression in various preneoplastic epithelial lesions and even reverse overt carcinoma.¹ Retinoids have also been shown to be potent inducers of granulocytic differentiation in a human promyelocytic leukemia cell line, HL-60,² and in blasts from patients with acute promyelocytic leukemia.³ Retinoids have been reported to inhibit the clonal growth of myeloid leukemic cells in vitro at pharmacologically achievable levels⁴ and to enhance the growth of normal myeloid and erythroid progenitors.^{5,6} These data suggest that retinoids might have clinical utility in the treatment of acute nonlymphoblastic leukemia (ANLL) by inhibiting the growth of the malignant clone, by enhancing normal stem cell proliferation, and, in some cases, by inducing terminal differentiation in the leukemic blasts. Because of the small numbers of cases of ANLL previously studied in vitro, we undertook an investigation of the effects of retinoic acid on the clonal growth and differentiation of leukemic cells from a larger group of patients and attempted to elucidate the mechanisms of action.

Assays for cellular retinoic acid-binding protein (CRABP) were performed on five samples (two with inhibitory growth responses, two with stimulatory responses, and one with no growth) and failed to reveal detectable levels of CRABP in any case. The addition of cisRA to liquid suspensions of leukemic cells produced no significant change in the number of viable cells. We conclude that the effects of cisRA on leukemic colony growth are not cytotoxic and not mediated by T lymphocytes, monocytes, or CRABP. More importantly, cisRA appears to enhance the growth of certain human leukemia cells in vitro. Taking into account the increasing use of retinoids in clinical trials for patients with leukemia, the latter findings may represent a significant cautionary note.

METHODS

Patients. Table 1 outlines clinical characteristics of the 35 patients studied. A breakdown by the French-American-British (FAB) classification shows a predominance of cases with FAB M-2 and M-4 morphology.⁷ Two cases of acute promyelocytic leukemia were studied. Most patients had received no prior therapy. The large number of patients with a previous history of a preleukemic condition (ten cases of myelodysplasia, one case of polycythemia rubra vera, and one case of Down's syndrome) reflects the link between our research interests and referral patterns. All patients involved in this study were advised of the methods and possible risks of marrow aspiration, in accordance with institutional guidelines, and gave informed consent.

Retinoic acid. 13-Cis-retinoic acid (cisRA) was kindly provided by Hoffman-LaRoche (Nutley, NJ) and was suspended in absolute alcohol at an initial stock concentration of 10^{-2} M and serially diluted in phosphate-buffered saline (PBS) to provide concentrations of 10^{-4} to 10^{-9} M. Control solutions containing ethanol alone were also prepared. CisRA and the controls were stored at -70°C in foil-wrapped tubes and were added to cultures under subdued light.

Leukemic cells. Heparinized samples of bone marrow or peripheral blood were obtained and light-density mononuclear cells isolated by a standard centrifugation step with Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ).^{8,9} In studies on the effect of T lymphocyte depletion, T cells were removed by rosetting with sheep erythrocytes (Prepared Media Laboratories, Tualatin, OR) and a second Ficoll-Hypaque separation.^{9,10} Monocyte depletion was accomplished by incubating cell suspensions in alpha medium and 10% fetal calf serum in large flat-bottomed flasks for 60 to 90 minutes at 37°C in a humidified 5% carbon dioxide atmosphere. Nonadherent cells were then removed by gentle pipetting and resuspended in their original volume.¹⁰

Blast colony assay. Leukemic blast colonies were grown using a modification of the methods of Minden et al¹¹ and Buick et al.¹² Agar underlayers were prepared in advance with 10% phytohemagglutinin-stimulated leukocyte-conditioned medium (PHA-LCM, see below) and varying concentrations of cisRA or ethanol. Leukemic cells were suspended in 0.9% methylcellulose with alpha medium and 20% fetal calf serum at 100,000 to 200,000 cells/mL and plated in 1 mL aliquots on each agar underlayer. Plates were wrapped loosely in foil and incubated at 37°C in a humidified 5% carbon dioxide atmosphere for seven days. Aggregates of five or more cells were counted as blast colonies and expressed as numbers per 100,000

cells plated. Three or four replicates were placed for each variable. A difference between variables was considered significant if the *P* value using a Student's paired *t* test was less than 0.05.

PHA-LCM. Buffy coat leukocytes were harvested from phlebotomy specimens of patients being treated for idiopathic hemochromatosis and placed in liquid suspension at 10^6 cells/mL with RPMI, 10% fetal calf serum, and 1% vol/vol phytohemagglutinin (Burlington Wellcome, Research Triangle Park, NC) by the method of Aye et al.¹³ Cell suspensions were incubated at 37 °C in a humidified 5% carbon dioxide atmosphere for three to five days. Supernatants were harvested and stored at 4 °C until used. Batches were screened for stimulatory activity, and samples from two donors were used for all studies because of their potency.

Assay for cytoplasmic retinoic acid-binding protein (CRABP).¹⁴⁻¹⁶ Cryopreserved leukemic cells from five patients (75 to 200 × 10⁶ cells per case) were rapidly thawed in a 37 °C water bath and washed twice in PBS, sonicated in KET-O buffer (1 mmol/L EDTA/10 mmol/L Tris-HCl, pH 7.4), and centrifuged at 159,000 × *g* for 45 minutes to obtain a supernatant (cytosol) fraction. The cytosols were first divided and diluted with KET-O or 6 mmol/L pCMBS (Sigma, St. Louis, MO) in KET-O to a final pCMBS concentration of 2 mmol/L and incubated for 30 minutes at 4 °C to block pCMBS-sensitive ligand binding to CRABP. The diluted cytosols were then evaluated for CRABP content as follows. Cells from the 3T6 murine fibroblast line were used as a positive control. For qualitative identification of specific retinoic acid binding to CRABP, 0.4 mL of diluted cytosol was incubated 22 to 26 hours in the dark at 4 °C with 50 nmol/L 35.9 Ci nmol [³H] retinoic acid (Hoffman-LaRoche, Nutley, NJ) alone or in the presence of a 200-fold excess of 0.01 mmol/L nonradioactive retinoic acid alone or in the presence of a 200-fold excess nonradioactive retinoic acid alone. Incubates were then analyzed by centrifugation on 4.6 mL 5% to 20% sucrose gradients at 234,000 × *g* for 22 hours. Radioactivity in five-drop fractions taken from the top of the gradients was counted in 5 mL of ACS scintillation cocktail (Amersham Corp, Arlington Heights, IL) at an efficiency of 26%. Sedimentation markers used were lactoglobulin (2.0 S), ovalbumin (3.7 S), and bovine serum albumin (4.4 S). For quantitative analysis, 100 μL aliquots of diluted cytosol or pCMBS-treated cytosol was then incubated for 24 hours at 4 °C with 0 to 100 nM [³H] retinoic acid, with the former set of incubations yielding total binding and the latter giving a measure of nonspecific binding. All points were run in duplicate and bound, and free retinoic acid was separated by adding 1 mL of 2.5% dextran T-70-coated charcoal in gelatin/phosphate buffer (0.15 mol/L NaCl/0.015 mol/L NaN₃/0.1 mol/L Na₂HPO₄/0.039 mol/L NaH₂PO₄, pH 7.03/0.1% gelatin). After 15 minutes, the charcoal suspension was centrifuged at 4,000 × *g* for 10 minutes and radioactivity in the supernatant was counted in 10 mL

of ACS cocktail (26% efficiency). In all cases cytosolic protein was determined by the method of Lowry et al.¹⁷

Studies of differentiation. Cytospin preparations were made from samples of leukemic blasts grown in liquid suspension (11 samples) or from leukemic colonies plucked from semisolid medium (three samples) with and without cis-retinoic acid 10⁻⁶ mol/L. Slides were stained with Wright-Giemsa stain (Camco Quik Stain, Cambridge Chemical Products, Ft. Lauderdale, FL). Differential counts were performed on 100 to 200 cells per slide. Cells were categorized by standard morphologic criteria either as primitive (blasts, promyelocytes, promonocytes) or as mature (myelocyte stage and beyond).

Nitro blue tetrazolium (NBT) reduction test was performed using standard methodology with phorbol myristate acetate (Sigma, St. Louis, MO) and Ficoll.¹⁸ After counterstaining with nuclear fast red, differential counts were performed on 100 to 200 cells per slide. Cells containing fine blue-black granules were scored as positive, and the percentage of positive cells was determined. A positive control using peripheral blood leukocytes from a normal donor was prepared with each batch of leukemic samples studied.

RESULTS

Blast colony assays. Clonal assays were attempted from 35 samples of leukemic blasts from patients with ANLL. Five samples showed no growth. Clonal efficiency varied widely with colony counts ranging from 0 to 1,920 per 100,000 plated cells. The median number of colonies was 89 (mean, 486). Unstained blast colonies had a characteristic morphology, forming very tight and usually spherical aggregates at the agar/methylcellulose interface. The average number of cells per aggregate was 10 to 20, although in some colonies the numbers exceeded 100. Wright staining of cytocentrifuge preparations or of air-dried colonies revealed aggregates of primitive cells with large nuclei with fine nuclear chromatin, prominent nucleoli, occasional cytoplasmic granules, and vacuoles without evidence of terminal differentiation. The cells within the colonies did not form rosettes with sheep erythrocytes.

Effects of retinoic acid on clonal growth. In three cases cisRA had no significant effect on clonal growth at concentrations of 10⁻⁷ to 10⁻⁶ mol/L. In 17 cases significant inhibition of colony growth was observed with cisRA at levels of 10⁻⁷ and 10⁻⁶ mol/L, both pharmacologically achievable levels (Table 2A). Inhibition ranged from 22% to 100% of the appropriate ethanol-containing controls with a median decrease of 69%. Inhibition increased with dose in eight of ten samples tested at multiple levels.

In ten cases we observed striking stimulation of colony growth ranging from 83% to 1500% of controls with a median increase of 176% (Table 2B). The control colony growth (medium of 129 and mean of 450 colonies per 100,000 plated cells) of these ten cases was not significantly different from the group as a whole. In seven cases the stimulation of growth increased with dose of cisRA. Figure 1 demonstrates a representative dose-response curve for a patient with enhanced colony growth. Ethanol had no effect on clonal growth except for the highest dose tested, whereas cisRA was strikingly stimulatory at levels of 10⁻⁷ – 10⁻⁵ mol/L. When T lymphocytes were removed before culture (lines with open circles), the effects of cisRA were essentially unchanged.

*Numerator represents mean number of colonies/100,000 cells plated in presence of cis-retinoic acid (CisRA). Denominator represents mean colony numbers in control dishes. All colony counts represent means of three to four replicates.

†Percentage difference was calculated by subtracting control colony growth from CisRA-treated colony growth and dividing by control colony growth.

‡Not significant by Student's *t* test ($P > 0.05$). All other differences have $P < 0.05$. ND, not done.

We studied the effects of T cell depletion in three additional cases, two with inhibitory responses and one with a stimulatory response, and found that the removal of T cells did not change the type of response in any case (data not shown). Two samples, one from a patient with an inhibitory response and one with a stimulatory response, were used to study the effects of monocyte depletion. In the former case, cisRA decreased colony growth from 38 to 20 colonies per 100,000 plated cells in the unfractionated portion and from

Fig 1. Effect of drug dose and T cell depletion on blast colony growth of cells from patient 19 with a stimulatory response. Results are expressed as absolute numbers of colonies per 100,000 plated cells. Light density cells grown in retinoic acid (●—●), light density cells grown in appropriate ethanol control media (○—○), T cell depleted cells grown in retinoic acid (○—○), T cell depleted cells grown in appropriate ethanol control media (○—○).

40 to 25 colonies/100,000 plated cells in the monocyte-depleted portion. In the latter case cisRA increased colony growth from four to 19 colonies/100,000 cells in the unfractionated portion and from four to 27 colonies/100,000 cells in the monocyte-depleted portion. Thus, monocyte depletion by an adherence procedure did not alter baseline blast colony growth nor the effect of cisRA.

Of the 17 patients with inhibitory responses to cisRA, only four had acute myelomonocytic leukemia (FAB-M4). Of the ten patients with a stimulatory response, seven had monocytic features. It appeared that cases with monocytic features more frequently displayed stimulatory responses than did other subtypes of leukemia ($P < .05$). Among the 12 samples from patients with a previous preleukemic condition, six were inhibited and five were stimulated by cisRA, and one sample showed no growth. Retinoid acid was inhibitory to colony growth in one case of acute promyelocytic leukemia and had no significant effect in the others.

CRABP assay. Cells from five patients, including two with stimulatory responses, two with inhibitory responses, and one with no growth (patient 18) were assayed for the presence of CRABP. Four of the five were evaluated qualitatively by sucrose gradient technique and found to be negative, ie, no specific 2S binding (Fig 2). All five were studied quantitatively by saturation analysis employing pCMBS and were found to have no measurable pCMBS-sensitive binding, indicating less than 0.5 pmol of CRABP per mg protein in all samples tested. By contrast, cytosol from 3T6 cells yielded specific 2S binding, which was inhibited by pCMBS and by an excess of unlabeled cisRA (Fig 2). The final protein concentrations in the incubation mixtures ranged from 0.3 to 0.5 mg/mL with median of 0.44 mg/mL.

Studies of differentiation. Liquid suspension cultures were prepared from leukemic cells from 18 patients. Cells were grown in alpha medium, 20% fetal calf serum, and 10% PHA-LCM with and without 10^{-6} mol/L cisRA. After seven days incubated cells were harvested and cytospin preparations were made. Among 17 samples (ten with inhibitory

Fig 2. Sucrose gradient analysis of binding of [^{3} H]retinoic acid to cytosol of (A) 3T6 cells (B and C) patients 3 and 5 with inhibitory response, (D) patient 22 with a stimulatory response, and (E) patient 33, whose cells did not form colonies. Cytosols were incubated with 50 nmol/L [^{3} H]retinoic acid alone (●), with 50 nmol/L [^{3} H]retinoic acid plus a 200-fold excess of unlabeled retinoic acid (○), or with 50 nmol/L [^{3} H]retinoic acid after treatment with pCMBS (▲).

responses and seven with stimulatory response in clonogenic assay) there was no difference in the percentages of primitive cells in retinoid-treated (median 90%, range 75% to 97%) and untreated samples (median 93.5%, range 78% to 100%). By contrast, the cells from one patient with APL showed striking granulocyte differentiation with cisRA (only 3% primitive cells as compared with 82% in control flasks).

In three cases blast colonies were plucked from the methylcellulose cultures and stained for morphologic evaluation. In two samples, one showing growth inhibition and one showing stimulation, cisRA treatment produced only primitive colonies composed entirely of blasts. In one case of APL, nine/11 colonies plucked from dishes containing cisRA were composed of mature cells while 12/12 colonies from untreated dishes were comprised of promyelocytes.

NBT tests were performed on 16 samples of leukemic cells after seven days of culture in liquid suspension with and without 10^{-6} mol/L cisRA. As can be seen in Table 3, retinoic acid did not significantly increase NBT positivity in any sample except the promyelocytic cell line HL60. Thus, with the exception of HL60 cells and cells from patients with APL, no patient's cells showed morphologic or functional evidence of differentiation in response to cisRA.

To exclude a nonspecific cytotoxic effect of retinoic acid on leukemic blasts, the numbers of viable leukemic cells after exposure to 10^{-6} mol/L cisRA in liquid suspension were determined. Cell cultures were set up at an initial cell concentration of 2×10^5 cells/mL. After four and seven days of incubation, aliquots of cisRA-treated and untreated sam-

ples were counted for numbers of viable cells with a hemocytometer and trypan blue exclusion. After four days of culture, there was no difference in cell numbers between retinoid-treated and untreated cells ($3.2 \pm 1.4 \times 10^5$ cells/mL v $3.4 \pm 1.7 \times 10^5$ cells/mL, 17 samples). Similarly, after seven days cell numbers were virtually identical ($4.8 \pm 2.6 \times 10^5$ cells/mL with cisRA v $4.5 \pm 2.5 \times 10^5$ with control, ten samples). Clearly there was no evidence that cisRA was cytotoxic in short-term culture. Furthermore, changes in cell numbers in liquid suspension had no correlation with retinoid-induced changes in clonogenic growth.

DISCUSSION

The results of this study indicate that mononuclear cells from blood or marrow of patients with ANLL will form aggregates of blast-like cells in a majority of cases. The fact that the cells in these aggregates do not form E rosettes and that colony counts were not significantly altered by T lymphocyte depletion excludes the possibility that the colonies arise from T lymphocytes contaminating the specimens. The lack of morphologic or functional features of mature granulocytes or monocytes makes it highly unlikely that these colonies arise from residual normal myeloid progenitors (CFU-GM). Previous studies have failed to demonstrate in vitro growth of normal CFU-GM from leukemic marrows.^{19,20}

The data demonstrate that cisRA significantly inhibits blast colony growth in most samples (17/30) of leukemic cells showing growth under basal conditions and that inhibition occurs at levels of the drug that can be achieved pharmacologically in man.^{21,22} However, the stimulation of growth in ten samples suggests that in some cases the drug might have an adverse effect on patients, especially since the growth enhancement seen in our cases was much greater than the twofold increase reported for normal hematopoietic stem cells grown in the presence of cisRA.^{5,6}

It is important to note that we observed no morphologic or functional evidence that cisRA induced differentiation in the leukemic samples we studied, whether growth was enhanced or inhibited, except for the two cases of acute promyelocytic leukemia. These observations are entirely consistent with those of Breitman et al³ who noted no evidence of maturation in human leukemic cells incubated with retinoids unless the cells had promyelocytic features. Our findings are perhaps more significant than Breitman's in that our observations were made on leukemic cells grown in the presence of colony-stimulating factors while his cultures were unstimulated.

The mechanisms of action of cisRA on leukemic growth are unclear. The effects appear not to be mediated by monocytes or T lymphocytes. It seemed important to exclude

a possible mediating role of auxiliary cells, since (a) monocytes and T cells elaborate cytokines, which stimulate the growth of normal and leukemic hematopoietic stem cells^{10,23,24}; (b) T cells may develop cytotoxicity for autologous leukemic blasts^{25,26}; and (c) retinoids enhance the immune functions of T lymphocytes.^{27,28} It is still possible that the effects of cisRA on our freshly obtained leukemic cells are mediated by other auxiliary cells such as B lymphocytes.

CRABP, a 2S protein with high affinity and specificity for retinoic acid,²⁹ has been considered a likely candidate as a mediator of the effects of the vitamin, since CRABP has been detected in breast cancer cells, embryonal carcinoma cells, neuroblastoma cells, melanomas, retinoblastomas, and other tumor cell lines and has been associated with both the antiproliferative and differentiation-induction effects of retinoic acid in those tumors.^{15,30-31} Although one group has reported the detection of CRABP in HL-60 cells,³² other groups have not found CRABP in HL-60 or any other myeloid leukemic blasts; hence it seems unlikely that normal CRABP is a mediator of the effects of cisRA in these cells.^{4,33}

Another potential fruitful area of investigation is the study of the effects of retinoids on oncogene expression in malignant cells. Other groups have reported marked decreases in *c-myc* and *c-myb* mRNA in HL-60 cells exposed to retinoids.^{34,35} Our own preliminary studies suggest that the effects of retinoids on oncogene expression in freshly obtained leukemic cells are complex.³⁶ Since oncogenes may play a role in cell proliferation and on the expression of the malignant phenotype, altering oncogenic expression in leukemic cells may inhibit cell growth and/or promote differentiation.

In our experience, in vitro responses to certain pharmacologic agents, including glucocorticosteroids, are predictive of in vivo responses to the same agents.^{37,38} Clinical trials of cisRA in leukemia, preleukemia, and smoldering leukemia have already been undertaken.³⁹⁻⁴³ Based on the observations, we fear that in some patients acceleration of the leukemic process may occur. We believe that therapeutic trials must include prospective in vitro testing of the effects of retinoids on leukemic cell growth to determine if growth patterns are predictive of clinical responses and, further, that if adverse in vitro responses correlate with adverse clinical responses, retinoid therapy should be ruled out in patients whose leukemic cells proliferate in response to the agent in vitro.

Proliferative and Differentiative Responses of B Cells From Human Marrow Graft Recipients to T Cell-Derived Factors

By Kosei Matsue, Lawrence G. Lum, Robert P. Witherspoon, and Rainer Storb

Upon activation, B cells express growth and differentiation receptors that permit them to proliferate and differentiate. The aim of this study is to define the nature of the intrinsic B cell defects found in marrow recipients using assays for B cell activation, proliferation, and differentiation. B cells from five short-term (< three months postgrafting) and 15 long-term (> one year postgrafting) marrow recipients (ten with and five without chronic graft-v-host disease [GVHD]) were studied. T cell supernatants (T-sup) were prepared by stimulating normal T cells with 12-O-tetradecanoyl-phorbol-13-acetate (TPA) and phytohemagglutinin. Highly purified B cells were used to assess B cell proliferation responses to T-sup after *Staphylococcus aureus* Cowan I (SAC) activation and for B cell immunoglobulin production responses to T-sup stimulation after SAC activation. B cells from all five short-term patients and one long-term patient with chronic GVHD did not respond to

any stimulation. B cells from two patients with chronic GVHD responded to SAC but had decreased proliferative and differentiative responses to T-sup. B cells from three of seven patients with chronic GVHD and two of five long-term healthy patients could proliferate but could not secrete immunoglobulin in response to SAC plus T-sup stimulation. Furthermore, there was a significant correlation between serum IgG and/or IgM in marrow recipients and the differentiative responses of their B cells to T-sup ($P = 0.0075$, Fisher's Exact). B cell defects occur at various stages of maturation postgrafting. These defects include the failure to respond to the SAC activation signal, the failure to proliferate in response to T-sup, and the failure to differentiate in response to T-sup. These findings are probably due to the inability of B cells from certain marrow recipients to undergo a second round of ontogeny.

© 1987 by Grune & Stratton, Inc.

RECENTLY it has been shown that B cell growth and differentiation is regulated by various lymphokines such as interleukin 1 (IL 1), interleukin 2 (IL 2), B cell growth factor (BCGF), B cell differentiation factor (BCDF), and the interferons.¹⁻⁸ Resting B cells can be activated by cross-linking of their immunoglobulin (Ig) molecules with multivalent ligands such as antigen, anti-Ig antibody, or protein A from *Staphylococcus aureus*. Upon activation, B cells express the receptors for BCGF and/or BCDF and, in the presence of T cell-derived factors containing BCGF and BCDF, go on to proliferate and terminally differentiate into Ig-secreting cells.⁹⁻¹¹

Marrow transplantation is being used for the treatment of hematologic malignancies, severe aplastic anemia, and some inborn errors with increasing success.¹²⁻¹⁵ However, marked immunodeficiencies associated with life-threatening opportunistic infections develop and may persist up to one to two years after grafting.^{16,17} Although numbers of T and B cells in the peripheral blood usually recover within one to three

months postgrafting, T and B cell collaboration is ineffective.¹⁸⁻²⁶ In vitro studies of marrow recipients using Ig biosynthesis stimulated with polyclonal activators revealed that there is functional heterogeneity within T cell subsets,^{23,24} normal monocyte function,²⁶ and intrinsic B cell defects in Ig production.⁹⁻²⁶ A recent study using an antigen-specific antibody production system showed that decreased antigen-specific B cell precursor frequency is one explanation for deficient antibody production in a minority of marrow recipients.²⁷ However, such data suggested that the majority of B cell defects were due to problems other than low antigen-specific B cell precursor frequency. These findings provided the rationale for studying B cells using a different approach.

Since nearly half of marrow recipients have B cells that failed to produce immunoglobulin, we chose assays for B cell proliferation and differentiation after *S aureus* Cowan I (SAC) activation that would identify the stages at which such defects occur. This investigation shows that B cells from marrow recipients have defects in SAC activation, defects in response to proliferative signals, and defects in response to differentiative signals.

METHODS

Patients. Twenty patients were studied between 63 and 1,736 days postgrafting. Five patients were studied at less than three months postgrafting (short-term), and 15 patients were studied more than one year postgrafting (long-term). Their unique patient number (UPN), age, sex, days of study after transplant, diagnosis, treatment at the time of testing, and serum Ig levels are presented in Table 1. These patients were conditioned for their marrow transplant as described.^{12,13,28} Nineteen patients received HLA-identical allogeneic marrow from their siblings. One patient (UPN 2590) received a syngeneic marrow graft. Posttransplant immunosuppression to prevent graft-v-host disease (GVHD) has been described.²⁸ The patient who received the syngeneic marrow graft did not receive postgrafting immunosuppression. Marrow engraftment was determined by red blood cell enzyme and antigen typing and by cytogenetic studies. All of these studies were done when the patients were clinically stable. Control subjects were healthy individuals or mar-

row donors. These studies were performed after informed consent was obtained under protocols approved by the Human Subjects Review Committees of the University of Washington and the Fred Hutchinson Cancer Research Center.

Cell separation. Peripheral blood lymphocytes (PBL) were obtained from 40 to 70 mL of whole heparinized blood by Ficoll-Hypaque (Pharmacia, Piscataway, NJ) density gradient centrifugation. Monocytes were removed from PBL by incubation for 30 minutes at room temperature with 5 mmol/L 1-leucine methyl ester (Sigma, St. Louis) in serum-free Mishell Dutton balanced salt solution.^{29,30} Monocyte-depleted PBL were then separated into T and non-T cell populations by rosetting with 2-aminoethylisothiuronium bromide (AET)-treated sheep erythrocytes.³¹ The non-T population was rosetted a second time with AET-treated sheep erythrocytes. The nonrosetting cells were further depleted of T cells by monoclonal antibody 35.1 (E rosette receptor antibody) and rabbit complement (Pel Freez, Roger, AR) to remove residual T cells. B cells obtained in this manner contained more than 72% B cells, less than 1% T cells, and less than 16% (mean = 5.0%) monocytes as determined by indirect immunofluorescence using monoclonal antibodies 299 (pan B), 35.1 (pan T), and 60.1 (antimonocyte), and fluorescein isocyanate-conjugated goat antimouse Ig (TAGO, Burlingame, CA). The monoclonal antibodies were gifts from Drs John Pesando and John Hansen at the Fred Hutchinson Cancer Research Center. These B cell-enriched fractions were designated B cells. The E rosetting cells (T cells) contained more than 95% E rosette-positive cells.

Generation of T cell supernatants containing BCGF and BCDF activity. Normal T cells at a concentration of 4×10^6 cells/mL in RPMI 1640 medium supplemented with 10% FCS were incubated with 5 ng/mL of 12-O-tetradecanoyl-phorbol-13-acetate (TPA, Sig-

ma, St. Louis) for two hours at 37 °C in 24 well plates (Catalog #1-43982, Nunc, Denmark). The T cells were then washed, resuspended in RPMI 1640 medium supplemented with 10% FCS, 1% penicillin-streptomycin, 4 mmol/L L-glutamine, and 5×10^{-5} mol/L 2-mercaptoethanol, and cultured for three days in the presence of phytohemagglutinin (1:640 dilution of stock, PHA, Difco) at a cell concentration of 2×10^6 /mL. The cell-free supernatants prepared in this manner were pooled from five individuals and stored at 4 °C until use. The T cell supernatant pool (T-sup) was screened for Ig by enzyme-linked immunosorbent assay (ELISA) and found to be <20 ng/mL. The T-sup contained 158 U/mL of IL 2 activity defined by titration on a CTLL murine cell line in comparison to recombinant IL 2.

Assay for B cell proliferation response. The ability of purified B cells to respond to BCGF contained in T-sup was assessed by using SAC (Pansorbin 10% vol/vol; Calbiochem-Behring Corp, San Diego, CA) stimulation following a modification of the procedure described by Muraguchi and Fauci.¹⁰ In brief, 1×10^5 B cells from normal subjects or marrow recipients were cultured in 0.2 mL of culture medium in the presence of 0.005% vol/vol SAC for three days in round-bottom microtiter plates (NUNC, Denmark). Then the culture media were replaced with fresh media containing various percentages of T-sup for three days. The cells were pulsed with 1 μ Ci [³H]-thymidine (New England Nuclear, Boston) for the last four hours. Incorporation of [³H]-thymidine was measured by standard liquid scintillation-counting techniques after harvesting the cells with a Titertek cell harvester (Flow Laboratories, Rockville, MD). B cell proliferative responses were assessed by comparing them with that of nine normal controls. In an arbitrary decision based on a relationship to the clinical status of the patients and a natural distribution of patient results above and below 30% of the median value, proliferative responses less than 30% of the median value of proliferative responses of normal B cells were considered defective.

Assay for B cell differentiation response. One hundred thousand B cells from normal subjects or marrow recipients were cultured in round-bottom microtiter plates in the presence or absence of SAC (0.005% vol/vol) and/or various dilutions of T-sup as indicated for ten days. B cell differentiative responses to T-sup were assessed by measuring culture supernatants for Ig. Supernatants from triplicate cultures were pooled, and the concentration of accumulated Ig in the culture supernatants was determined by ELISA assays specific for human IgG, IgM, and IgA.^{32,33}

Immunoglobulin production by B cells from patients was compared with that of 9 normal controls. In an arbitrary decision based on a relationship to the clinical status of the patients and a natural distribution of patient results above and below 20% of the median value, immunoglobulin production responses less than 20% of the median value of immunoglobulin produced by normal B cells were considered defective.

RESULTS

Proliferative responses of normal B cells to T-sup. Experiments were initially undertaken to determine the BCGF and BCDF activities present in the T-sup. The representative experiment in Fig 1 shows that SAC-stimulated B cells from a single individual gave a maximal response on day 3 that fell to essentially background by day 6. When T-sup were added to such cultures on day 3, the SAC-activated proliferative responses of B cells were sustained through day 8. These data show that T-sup supports B cell proliferative responses. Figure 2 shows B cell proliferative responses as a function of the reciprocal dilution of T-sup. Similar results were obtained when B cells from marrow recipients were

Fig 1. Kinetics of the proliferative response of B cells to SAC, T-sup, and SAC plus T-sup in a normal subject. One hundred thousand purified B cells were cultured with SAC (0.005 % vol/vol), T-sup (25%), or SAC plus T-sup for the indicated periods of time. SAC was added on day 0 and T-sup was added on day 3. The cultures were pulsed with [^3H]-thymidine four hours before harvest. The data points represent the mean $\pm$ 1.0 SD for triplicate cultures.

examined. From these data we chose a 1:4 dilution of T-sup for use in the B cell proliferation assay.

To exclude T cell contamination or proliferation during the culture, we examined the PHA-induced proliferative responses of B cells and the percentages of E rosette-positive cells at the end of cultures. The median proliferative responses of B cells to PHA stimulation from various study groups expressed as stimulation indices are 1.4 (range 0.3 to 2.4) in the normal control group; 0.8 (range 0.3 to 1.4) in short-term marrow recipients; 1.2 (range 0.4 to 1.8) in long-term recipients with chronic GVHD; and 1.2 (range 0.4 to 1.8) in long-term recipients without chronic GVHD. Only a small proportion of E rosette positive cells (0% to 2.0%)

Fig 2. The relationship between the magnitude of B cell proliferation as a function of T-sup concentration in a normal subject. $\bullet$ = 100,000 B cells were cultured with SAC (0.005 % vol/vol) for three days and an additional three days with serial dilutions of T-sup. $\circ$ = 100,000 B cells were cultured with media for three days and an additional three days with serial dilutions of T-sup. The cultures were pulsed with [^3H]-thymidine four hours before harvest. The data points represent mean $\pm$ 1.0 SD of triplicate cultures.

Fig 3. Effects of SAC, T-sup, and SAC plus T-sup on Ig production using purified B cells from seven normal subjects. One hundred thousand B cells were cultured with medium, SAC (0.005 % vol/vol), T-sup (0.03125 %), or SAC plus T-sup for ten days. Supernatants from triplicate cultures were pooled, and total Ig (IgG + IgM + IgA) produced was quantitated by ELISA. The median values of each group are indicated with ($\leftarrow$).

were present at the end of such cultures. Therefore, the proliferating cells were B cells and not contaminating T cells.

Differentiative responses of normal B cells to T-sup. B cell differentiation (Ig production) was assessed by SAC, T-sup, or SAC plus T-sup stimulation. The effects of T-sup on the differentiation of normal B cells were examined by quantitating Ig production in culture supernatants stimulated with SAC or T-sup alone or SAC plus T-sup. Figure 3 summarizes the results of seven separate experiments. Stimulation of B cells by SAC or T-sup alone occasionally induced detectable amounts of Ig in the culture supernatants. However, co-stimulation with SAC and T-sup consistently induced larger amounts of Ig than stimulation with SAC or T-sup alone. These results are similar to those reported in earlier studies.^{4,30}

In contrast to the B cell proliferation assay, the optimal concentrations of T-sup for Ig biosynthesis were much lower. Maximal Ig biosynthesis of IgG, IgM, or IgA occurred at a concentration of 3.125% (1:32). Higher or lower concentrations of T-sup in the cultures did not support Ig synthesis as well as the 1:32 dilution of T-sup (Fig 4). Similar results were obtained when recipient's B cells were examined. Therefore, a final concentration of 3.125% of T-sup was used for all subsequent B cell differentiation assays.

B cell proliferative responses to SAC in normals and marrow recipients. SAC-stimulated B cell proliferation responses are shown in Fig 5 for marrow recipients and control subjects. Purified B cells were stimulated with SAC

Fig 4. Immunoglobulin production by B cells from a normal subject as a function of the concentration of T-sup. One hundred thousand B cells were cultured with SAC (0.005 % vol/vol) and serial dilutions of T-sup for ten days. Supernatants from triplicate cultures were pooled and class-specific Ig production was quantitated by ELISA.

Fig 5. B cell proliferative responses to SAC in normal subjects and three groups of marrow recipients. N (●) represents the normal subjects, P1 (○) represents the short-term recipients, P2 (△) represents the long-term recipients with chronic GVHD, and P3 (□) represents the healthy long-term recipients. One hundred thousand B cells were cultured with SAC (0.005%) for three days and were pulsed with [³H]-thymidine for four hours before harvest. Each point represents the mean value of triplicate cultures. Mean values for each group were indicated with (—) and vertical bars represent one SD above and below the means.

for three days, and their proliferative responses were measured by [³H]-thymidine incorporation. Figure 5 shows that B cell proliferative responses to SAC are impaired in short-term recipients but not in long-term recipients with or without chronic GVHD.

B cell proliferative responses to T-sup after SAC activation in normals and marrow recipients. The proliferative responses of SAC-stimulated B cells from nine normal control subjects and from 20 marrow recipients were examined (Table 2). The T-sup (obtained from normal subjects) consistently maintained the proliferative responses of normal B cells after SAC activation, whereas SAC prestimulated B cells from all short-term recipients failed to proliferate in response to T-sup. One (UPN 2534) of ten long-term recipients with chronic GVHD had B cells that could not respond to any stimulation. Two patients (UPN 2416 and 1531) had B cells that responded to SAC normally but failed to maintain proliferative responses to T-sup after SAC stimulation. Seven of ten long-term recipients with chronic GVHD and all five healthy long-term recipients had B cells capable of responding to T-sup after stimulation with SAC.

B cell differentiative responses to T-sup in normals and patients. Recipient's B cells showed variable responses to SAC and T-sup co-stimulation, whereas normal B cells consistently resulted in increased Ig production in response to SAC and T-sup co-stimulation (median 14.6 µg/mL, range: 7.1 to 42.8 µg/mL) as shown in Fig 6. B cells from marrow recipients did not produce Ig spontaneously or respond to either SAC or T-sup alone (data were not shown). IgG and IgM were the predominant immunoglobulin classes produced, while lesser amounts of IgA were produced by B cells from normal subjects and marrow recipients.

Control B cells from normal subjects stimulated with SAC and T-sup together produced large amounts of immunoglobulins. In contrast, B cells from short-term recipients produced small amounts of immunoglobulin in response to co-stimulation with SAC and T-sup. Six of ten long-term recipients with chronic GVHD had B cells with poor Ig production responses to co-stimulation with SAC and T-sup. Three of these recipients had B cells that could not proliferate after either SAC or SAC plus T-sup co-stimulation, and the other three recipients had B cells that could proliferate but could not differentiate in response to SAC plus T-sup co-stimulation. B cells from the other four long-term recipients with chronic GVHD showed normal differentiative responses. Two of five healthy long-term recipients had B cells that failed to produce Ig in the range defined by normal B cells, although their B cells were able to proliferate after SAC and T-sup co-stimulation. B cells from the other three recipients without chronic GVHD showed normal differentiation responses.

Types of distribution of abnormalities. Table 3 summarizes the types and the distribution of various B cell abnormalities observed after marrow grafting. B cells from all three groups of patients showed B cell defects at one or more steps in the maturational scheme. These abnormalities include defective responses to SAC activation and failure to proliferate and/or differentiate in response to T-sup. There was no correlation between the magnitude of proliferative

‡Cultures stimulated with T-sup alone for three days.

§Cultures activated with SAC for three days and then T-sup added for the last three days (total of six days of culture).

responses and the amount of Ig produced. However, immunoglobulin production was not observed in the absence of proliferative B cell responses. These abnormalities were found less frequently in B cells from long-term healthy recipients.

Correlation of serum immunoglobulin levels and B cell differentiation ability. Serum immunoglobulin levels in long-term marrow recipients were compared with in vitro immunoglobulin biosynthesis responses of B cells after SAC and T-sup stimulation. In vitro B cell differentiation responses to co-stimulation with SAC and T-sup were significantly correlated with the presence or absence of low serum IgG or IgM levels but not IgA levels (Fisher's exact test $P = 0.0075$).

DISCUSSION

This study demonstrates that B cell defects occur at various levels of differentiation in marrow transplant recipients. These defects include impaired proliferative responses

to SAC antigen and the inability to proliferate and/or differentiate in response to T-sup containing BCGF and BCDF activities. Such B cell defects in marrow recipients have not been reported in the literature.

Previous studies in our laboratory revealed intrinsic B cell defects in marrow graft recipients using polyclonal activators^{21–26}; however, the intrinsic defects of B cells have not been further defined. The proliferation and differentiation of B cells in response to pokeweed mitogen and other polyclonal activators is totally or partially dependent on the accessory cell function of monocytes and the presence of helper T cells.³⁴ For these reasons it has been difficult to identify the specific stage(s) of B cell defects in the maturation processes.

T cell-dependent signals for B cell proliferation and differentiation can be completely replaced by soluble factors such as BCGF and BCDF, thereby permitting the dissection of B cell maturation processes in the absence of accessory cells. Since the BCGF, BCDF, PHA, and IL 2 in crude T cell

Fig 6. B cell differentiation responses to T-sup after SAC activation in normal subjects and three groups of marrow recipients. N (●) represents the normal subjects, P1 (○) represents the short-term recipients, P2 (Δ) represents the long-term recipients with chronic GVHD, P3 (□) represents the long-term recipients without chronic GVHD. Median values for each group are indicated with (—). One hundred thousand B cells were cultured with SAC (0.005 % vol/vol) and T-sup (3.125%) for ten days. Supernatants from triplicate cultures were pooled and Ig production was quantitated by ELISA. Experimental values below the dashed lines ($\leq 20\%$ of normal median values for IgG, IgM, IgA and total Ig) were considered defective.

“+” denotes a normal response and “—” denotes a deficient response. Deficient response is defined by less than 30% of median value of normal in proliferative response and less than 20% of median value of normal in total Ig production.

supernatants may cause T cell proliferation, and monocytes in the non-T cell fractions may inhibit the B cell responses to T cell factors.^{35,36} Vigorous depletion of T cells and monocytes from B cell-enriched fractions was necessary. Our results show that B cell fractions had nearly background responses to PHA stimulation. However, we could not exclude the possibility that the soluble factor(s) such as IL 2 in the T-sup stimulated small numbers of contaminating T cells to proliferate or secrete other factor(s) that in turn may modulate B cell proliferation or differentiation. Howard et al³⁷ demonstrated that IL 2-stimulated T cells secrete BCGF. Recent studies demonstrated that activated B cells express IL 2 receptors and can proliferate and differentiate in response to recombinant IL 2.⁵⁻⁷ These data support the notion that IL 2 is acting as a growth and differentiation factor for B cells. Since IL 2 was not absorbed from T-sup containing BCGF and BCDF activity and highly purified preparations of BCGF and/or BCDF were not available, our results likely represent B cell reactivity to BCGF, BCDF, and also to IL 2. The effect of recombinant IL 2 on the growth and differentiation of B cells from marrow recipients is under investigation.

B cells from all short-term recipients and one long-term recipient with chronic GVHD failed to show appreciable responses to any stimulation. The cause of this type of B cell defect is unknown, but it is possible that these B cells could not bind SAC or transmit the SAC activation signals. These B cells would presumably fail to express receptors necessary for proliferation and differentiation due to a defect in SAC activation. We hypothesize that the defect in SAC activation is the result of a maturational arrest that occurs early in B cell ontogeny. Ault et al³⁸ described an unusual B cell observed shortly after transplant that expressed B markers (sIg+ and B1) and the CD5 antigen but no other T cell antigens. This B cell bearing the CD5 antigen was also found

in fetal spleen and did not respond to pokeweed mitogen stimulation by producing Ig.³⁹ The lack of in vitro function and time of appearance after marrow grafting suggest that these CD5 positive B cells may be associated with the unresponsiveness of recipient B cells to SAC activation observed after marrow grafting.

In some long-term recipients, B cells were unable to proliferate and/or differentiate in response to T cell supernatants even though they showed initial proliferative responses to SAC. Although the causes of such defects are unknown, it is reasonable to postulate that such B cell defects may be due to the failure to express receptors for proliferation and/or differentiation factors after SAC activation or due to post-receptor abnormalities within the B cells. Another possibility is that low-level monocyte contamination may account for deficient B cell proliferation and differentiation. In a previous study²⁶ we found that some recipient monocytes could suppress Ig production from normal B cells in the pokeweed mitogen system. These results are consistent with our previous studies in that B cells from nearly all short-term patients, one-half of the long-term recipients with chronic GVHD, and roughly one-third of the long-term recipients without chronic GVHD could not differentiate into Ig-secreting cells in the presence of normal helper T cells in the pokeweed mitogen-stimulated cultures.²¹⁻²⁶

Although the B cell defects delineated herein have not been previously described, similar findings were observed in patients with common variable immunodeficiency (CVI). Saiki et al⁴⁰ reported that a group of CVI patients showed normal B cell proliferation to SAC but failed to differentiate in the presence of T cell factor. However, they did not evaluate B cell proliferation to T cell factor after SAC activation. Recently Perri and Weisdorf⁴¹ reported a case of a CVI patient with a defective response to BCGF. Such defects in B cells from marrow recipients and CVI patients may contribute to the impaired in vivo humoral antibody responses.

On the other hand, Saxon et al⁴² reported three cases of chronic GVHD patients with hypergammaglobulinemia who had B cells that spontaneously synthesized Ig in vitro. They postulated that activation and terminal differentiation of B cells occurred during chronic GVHD. In a separate series of experiments we also observed a similar case of a marrow recipient with chronic GVHD who showed hypergammaglobulinemia and increased spontaneous IgG production in vitro (unpublished observation).

In previous studies using the pokeweed mitogen and tetanus toxoid systems, we could not show any correlation between in vivo and in vitro antibody production. This study shows a significant correlation exists between in vivo serum Ig levels and in vitro differentiation responses of B cells in long-term recipients. These findings suggest not only that the assay systems used in this study more accurately reflect in vivo B cell function than PWM or tetanus toxoid-stimulated systems but also that B cell differentiation defects are a major cause of defective antibody responses seen in vivo after marrow transplantation.

Taken together our present results and other studies show that B cell deficiencies occur at various levels of differentiation following bone marrow transplantation. Further studies using monoclonal antibodies directed at the receptor(s) for BCGF and BCDF and the use of recombinant preparations of various B cell active lymphokines may provide important insights into these abnormalities. The results of such studies may eventually permit the use of recombinant forms of BCGF and/or BCDF for therapeutic intervention in marrow transplant recipients and immunodeficiency disorders.

ACKNOWLEDGMENT

The authors express their appreciation to Jan Noges for her careful reading of this manuscript and to the support staff in the bone marrow transplant units and long-term follow-up staff in the Outpatient Department for obtaining the samples necessary for performing these studies.

Ektacytometric Measurement of Sickle Cell Deformability as a Continuous Function of Oxygen Tension

By Martin P. Sorette, Marc G. Lavenant, and Margaret R. Clark

In an effort to study the rheologic effects of small amounts of hemoglobin S (HbS) polymer in sickle red cells, we have used the ektacytometer, a laser diffraction couette viscometer, to measure sickle cell deformability as a function of oxygen tension. Sick cell populations of defined intracellular hemoglobin concentration (MCHC) were isolated using Stractan density gradients and were resuspended in buffered polyvinylpyrrolidone solutions for deformability measurements. Using a gas-porous, hollow fiber gas exchange system to establish a linear gradient in oxygen tension, deformability was measured over a pO_2 range of 76 to 0 mm Hg. Parallel spectroscopic determinations of oxygen saturation permitted determination of cell de-

mability as a function of oxygen saturation for each discrete MCHC population. From these measurements the level of oxygen saturation at which a loss in cell deformability was first detected could be defined. Then, using the data of Noguchi and Schechter,⁹ the amount of polymerized HbS in the cells at that defined level of oxygen saturation was estimated. The results of this analysis suggested that the quantity of polymer that caused a detectable loss in cell deformability increased with increasing MCHC. In addition, for MCHC above 30 g/dL, this represented a substantial fraction of the total HbS in the cell.

IT IS WIDELY ACCEPTED that the pathologic manifestations of sickle cell disease arise from abnormalities in blood rheology that ultimately derive from the formation of rigid hemoglobin S (HbS) polymer within the cells. Several different factors that influence blood rheology could potentially contribute to clinical problems: acute loss of deformability in red cells that develop polymer at low oxygen tension¹⁻³; chronically impaired deformability of red cells that have been dehydrated, possibly as a result of previous polymerization episodes⁴; impaired capillary blood flow because of increased adherence of sickle red cells to the endothelial lining of the vessels⁵; as well as factors other than sickle red cells that modulate the function of the microvasculature.⁶ Recently nuclear magnetic resonance (NMR) studies have provided evidence that sickle cells from the upper end of the distribution in mean cell hemoglobin concentration (MCHC) maintain polymeric HbS even at relatively high levels of oxygen saturation.⁷⁻⁹ On this basis it has been suggested that the continuous presence of polymer in circulating sickle cells may provide a dual hazard. First, pre-formed polymer would eliminate any delay in formation of more polymer in the event of a rapid transient reduction in oxygen tension; and second, the residual polymer might itself impair the deformability of the red cell, reducing its ability to circulate through the microvasculature.

In an effort to evaluate the physiologic significance of this latter possibility, we have employed a means of measuring sickle cell deformability at low oxygen tension similar to those used by Johnson et al.,¹⁰ Bessis et al.,¹¹ and Feo et al.¹² By

measuring the loss of cell deformability as a continuous function of oxygen tension, we have sought to determine the effect of a relatively defined intracellular concentration of HbS polymer on red cell rheology.

MATERIALS AND METHODS

After obtaining informed consent, as approved by the Human and Environmental Protection Committee of the University of California, San Francisco, blood samples were drawn into acid-citrate-dextrose (ACD) or EDTA. Patients were identified as being homozygous for HbS on the basis of hemoglobin electrophoresis and family studies performed by the Northern California Comprehensive Sickle Cell Center. To measure red cell deformability we used the ektacytometer, a laser diffraction couette viscometer that has previously been described in detail.¹³ For the present experiments the instrument was coupled to a gas exchange system similar to that described by Schmuklar and Chien,¹⁴ which permitted the preparation of cell suspensions at defined oxygen tension (Fig 1). The gas exchange system was a bundle of 200 μ m diameter gas-porous, hollow fibers (Celgard type X-10 MHF; Celanese Corp, Charlotte, NC), around which flowed a humidified mixture of nitrogen and oxygen at the desired oxygen tension. The fibers were sealed into an airtight plexiglass housing with gas-tight compression fittings at the entry and exit ports. The red cells, suspended in a solution of 4% (wt/vol) polyvinylpyrrolidone (PVP) in isotonic buffered salt solution, were pumped through the fibers by a Harvard infusion pump (Model 600-000, Harvard Apparatus Co, Dover, MA) at a rate of 3.8 mL/minute. The suspension then flowed into a length of oxygen-impermeable tubing (Nyliflow pressure tubing 1/8 in, Polymer Corp, Reading, PA) immersed in a water bath at 37 °C, where it was held for varying periods to permit polymer formation. In normal operation a proportional metering valve was used to vary the proportion of oxygen to nitrogen in the gas exchange mixture over a chosen range as the cell suspension flowed through the gas exchange system. The fibers in which gas exchange occurred contained a cell suspension volume of 2.7 mL, and the full gradient of 76 mm Hg was established over a cell suspension volume of 30 mL. Once the oxygen gradient was established along the flowing cell suspension, the cells passed into a length of small diameter, gas-impermeable tubing, where they were equilibrated at 37 °C to permit polymer formation. The oxygen gradient was found to be maintained along the tube length for periods up to 90 minutes.

After equilibration the cell suspension was pumped past an oxygen electrode (Model E 5046; Radiometer, Copenhagen) fitted with a high sensitivity rapid response membrane (Yellow Springs Instru-

ment Co, Yellow Springs, OH) and then into the bottom of the ektacytometer chamber. Aspiration of the flowing suspension from the top resulted in an upward flow through the annular space between a stationary and a rotating cylinder. A viscometer rotation speed of 100 rpm generated a laminar shear stress field of approximately 100 dynes/cm² for 4% PVP concentration. This level of shear stress, at the upper range of that expected *in vivo*,¹⁵ was selected because it would induce deformation of nearly all normal red cells, whereas high MCHC normal and sickle cells would not deform at lower applied shear stress. It should be noted that deformation under these conditions does not imply that the cells deform readily *in vivo*. A laser beam passing through the cell suspension was diffracted by the cells, and a photometric detector provided a deformability index (DI) signal. This signal can be decreased in either of two instances.¹³ First, a subpopulation of cells could become undeformable, and a double diffraction pattern representing both deformable and undeformable cells would be seen. Alternatively, the entire cell population might show a homogeneous reduction in the extent of deformation, producing a single diffraction pattern. In these experiments a double diffraction pattern was observed over the range of decrease in the DI signal, indicating that cells either deformed fully or failed to deform. Therefore, the DI signal gave a measure of the proportion of deformable cells that persisted at any given pO_2 .

For each deformability measurement, approximately 250 μ L of packed cells were suspended in 50 mL of isotonic PVP-buffer solution (0.5% hematocrit). The cation composition of the buffer was chosen to match the average intracellular concentrations (in mEq/L cell water) of the sickle cell samples. The purpose of this was to minimize the transmembrane gradients for Na and K, thereby preventing changes in intracellular ion and water content once the cells sickled and became more permeable to cations. On the basis of flame photometric measurement (Instrumentation Laboratories Model 443, Lexington, MA) of the sodium and potassium content of sickle cells washed in isotonic Tris-buffered (10 mmol/L, pH 7.4) $MgCl_2$ solutions, we used a medium containing 17 mmol/L NaCl, 50 mmol/L KCl, and 10 mmol/L Na phosphate, pH 7.4 or 7.2. Sucrose was added to a concentration of 123 mmol/L to adjust the osmolality to 290 mosm/kg. The addition of PVP has a negligible effect on osmolality. In most experiments the concentration of PVP was 4 g/100 mL of buffer, but in some experiments the concentration was varied to determine the effect of suspending medium viscosity. The viscosity of the PVP solutions at 37 °C was measured using a capillary viscometer.

To relate the observed changes in cell deformability to oxygen tension, the DI signal was applied to the Y axis of an XY recorder, while the signal from the oxygen electrode was applied to the X axis.

The oxygen electrode was calibrated using flowing PVP-buffer solutions that had been equilibrated with defined gas mixtures.

In these experiments, for each set deformability measurements it was important to know the actual concentration of deoxy HbS within the cells as a function of oxygen tension. To determine this we prepared cell suspensions along the oxygen gradient exactly as for the ektacytometric measurements, but after the equilibration period pumped them through a flow-through cuvette in a Beckman DU7 spectrophotometer (Beckman Instruments, Palo Alto, CA). As the cells flowed past the oxygen electrode and through the cuvette, repeated measurements of absorbance at 540, 560, and 576 nm were made for every 3.8 mm Hg change in pO_2 . Using fully deoxygenated and fully oxygenated cell suspensions, a correction for light scattering by the cells was determined. The corrected absorbance data were then used to calculate the percentage of deoxyhemoglobin at each time point, using the equations of Benesch et al.¹⁶ Care was taken to ensure that the cell suspension volume between the oxygen electrode and the light path in the cuvette was the same as the corresponding volume in the parallel ektacytometric experiments. This obviated the need to correct for the spatial separation of the viscometer and the oxygen electrode when DI data were related to oxygen saturation. The measured values of oxygen saturation and MCHC were then used to estimate intracellular polymer content at the values of oxygen tension at which deformability changes occurred, using data from Noguchi.¹⁷ This involved taking interpolated values from the graphic representation of their calculated curves for polymer fraction as a function of oxygen saturation for cells of various MCHC over the range of 24 to 48 g/dL. To permit use of this approach, which does not take into account the presence of hemoglobins other than HbS, only samples containing low HbF (<8%) were used in this analysis.

Whole sickle blood contains cells covering a broad range in MCHC, which has a large effect on HbS polymerization. Therefore we used density gradient centrifugation to isolate more homogeneous MCHC populations in which polymer content could be more closely defined. We used arabinogalactan (Stractan II; St Regis Paper Co, Tacoma, WA)¹⁸ to prepare discontinuous gradients, using six layers ranging in equal steps from 1.085 to 1.110 g/mL density, layered onto a cushion of at least 1.133 g/mL density. The gradients were centrifuged in a Beckman L3-50 ultracentrifuge (Beckman Instruments, Palo Alto, CA) for 30 minutes at $74,000 \times g$ at 20 °C. The separated cells were collected from the gradient interfaces using a Pasteur pipet and were washed three times in buffered saline containing glucose and potassium (135 mmol/L NaCl, 5 mmol/L KCl, 8.6 mmol/L Na_2HPO_4 , 1.4 mmol/L NaH_2PO_4 , and 11 mmol/L glucose, adjusted to pH 7.4 and 290 mosm/kg) before use. MCHC was determined from a spun hematocrit and spectrophotometric measurement of hemoglobin as the cyanomethemoglobin complex. Fetal hemoglobin was quantitated using isoelectric focusing techniques.¹⁹ For evaluation of sickle cell morphology, a double gas exchange system was constructed so that glutaraldehyde solutions and red cell suspensions could be adjusted to identical pO_2 . The effluent from both sets of fibers was then brought together to fix the cells without altering their oxygen saturation. The percent of sickled cells was determined from counts of 500 cells.

RESULTS

When a gradient in oxygen concentration from 76 to 0 mm Hg was established along a flowing suspension of sickle cells and the cells allowed to equilibrate for 30 minutes, they showed the expected oxygen concentration-dependent reduction in the ability to deform under shear stress, as shown in Fig 2. The DI v pO_2 curves showed a constant, maximal DI

Fig 2. Variation in deformability signal (DI) as a function of oxygen tension for a Fraction 2 gradient population. As shown here, cell deformability decreased abruptly over a relatively narrow range in pO_2 , producing a curve that essentially represented two intersecting lines. The point of intersection was used to define the pO_2 at which loss of deformability was first detected (pO_2^*). Reduction of the pH from 7.4 to 7.2 shifted this critical pO_2 to higher values, reflecting the pH-induced increase in HbS polymerization.

down to a critical pO_2 level, after which it decreased in essentially linear fashion. Thus, the intersection of the two linear portions of the curve was used to identify the pO_2 value at which a loss of deformability was first detectable (designated pO_2^* in Fig 2). In addition, because this value was expected to vary with MCHC, we also used the pO_2 at which the DI fell to a value of 0.2 to characterize each curve. The data shown in this figure and in Figs 3 through 5 were obtained on cell populations collected from the interface between the first and second layers of Stractan (Fraction 2). Such density-separated cell populations displayed a sharper transition in deformability with oxygen tension than whole blood, as expected from their greater homogeneity (data not

Fig 3. Effect of suspending medium viscosity on the DI v pO_2 curve for a Fraction 2 gradient population. A decrease in viscosity below 19.5 cp at 37 °C cp (4% PVP concentration) resulted in overall reduction in cell deformation and eventual blurring of the deoxygenation-dependent loss of cell deformability. (-----) 19.5 cp, (—) 12.5 cp, (—) 9.5 cp, (·····) 7.5 cp.

Fig 4. Comparison of DI v pO_2 relationship for continuous pO_2 gradient (continuous curve) and for measurements performed at fixed pO_2 values (open circles) over the same range for a Fraction 2 gradient population.

shown). It can be seen that these Fraction 2 samples in the various experiments did not give identical DI v pO_2 curves. Comparison of the oxygen dissociation curves for the samples showed that differences in oxygen affinity, presumably due to individual patient differences and differences in cell storage time, were the major source of variation.

A series of experiments was performed to determine the effect of important experimental variables and to define the optimal procedure to obtain reproducible, physiologically relevant data. As expected from the characteristics of the polymer equilibrium, several factors predictably affected the range of oxygen tension over which the cell deformability loss occurred. Reduction of the suspending medium pH from 7.4 to 7.2 caused a parallel shift of the DI v pO_2 curve to higher pO_2 (Fig 2), consistent with the increased Bohr effect of HbS, particularly below an extracellular pH of 7.4, and the corresponding enhancement of polymer formation.^{4,20} Most of the experiments employed paired deformability and oxygen saturation measurements at both pH 7.2 and 7.4 to permit comparison of the results with those of Noguchi et al⁷ and Noguchi¹⁷ on polymer content, since those experiments

Fig 5. Relationship between the reduction in the DI signal and percentage of sickle cells for a Fraction 2 gradient population.

were performed at pH 7.2. Some additional experiments were performed only at pH 7.4.

The position of the DI v pO_2 curve also varied with MCHC, as shown by measurements using subpopulations of sickle cells isolated on density gradients (Fig 6). Again, the shift of the curves to higher pO_2 with increasing MCHC was consistent with the known increase in polymer content with increasing MCHC for any given oxygen tension.^{4,21} The DI versus pO_2 curves for unseparated cells (data not shown) were always broader than those for the gradient populations, reflecting the fact that the heterogeneous mixture of cells underwent polymerization and sickling over a broad pO_2 range.

Another variable that influenced the position of the DI v pO_2 curve was the viscosity of the suspending medium. A decrease in extracellular viscosity, achieved by reducing the concentration of PVP, resulted in a reduction in the proportion of deformable cells at progressively higher pO_2 values. For higher MCHC cells there was also a reduction in the maximum attainable DI (Fig 3). We attribute this latter effect to the requirement for a threshold ratio of extracellular to intracellular viscosity to induce red cell deformation.²² A viscosity of 19.5 cp (4% PVP at 37 °C) was chosen for subsequent experiments, since this viscosity showed clear-cut deformability differences among normal red cells from different density gradient subpopulations without introducing large variations among whole blood samples from different normal subjects. It was found that if the viscosity was reduced much below 19 cp, a substantial and varying proportion of cells from normal individuals would not deform, leading to a broadening of the range of normal isotonic DI values.

Other experimental variables tested for their effect on the deformability-oxygen tension relationship included the cation composition of the suspending medium, the flow rate of the cell suspension through the gas exchange fibers, and the time period between gas exchange and deformability measurement. When cells were equilibrated in high-Na,

Fig 6. DI v pO_2 curves for Fractions 1 to 4 of Stractan-separated sickle cells. As the MCHC of isolated cell populations increased, the maximum DI decreased, and a deoxygenation-dependent loss in cell deformability occurred at progressively higher pO_2 . See Table I for characteristics of the cell populations.

Table 1. Characteristics of Sickle Cell Gradient Subpopulations

Fraction	MCHC (g/dL)	Reticulocytes (%) ($\bar{X} \pm \text{SEM}$)	ISC (%)
1	26.00 $\pm$ 0.72	10.95 $\pm$ 1.14	2.12 $\pm$ 0.29
2	29.49 $\pm$ 0.44	7.84 $\pm$ 1.09	2.95 $\pm$ 0.48
3	31.21 $\pm$ 0.47	5.59 $\pm$ 0.55	3.82 $\pm$ 0.46
4	33.20 $\pm$ 0.47	4.22 $\pm$ 0.55	5.95 $\pm$ 0.60
5	34.75 $\pm$ 0.37	2.83 $\pm$ 0.80	7.58 $\pm$ 0.93
6	39.48 $\pm$ 0.91	1.40 $\pm$ 0.19	12.59 $\pm$ 1.08

low-K medium, the DI- pO_2 curve was shifted to higher oxygen tensions as compared to the curve obtained for cells from the same sample that were equilibrated in a medium in which the Na and K concentrations were close to their intracellular concentrations. This difference was interpreted as a reflection of a net leakage of K ions out of sickled cells in the high Na medium, resulting in a loss in cell water and a concomitant increase in HbS concentration and polymer content. Therefore the buffer that minimized transmembrane cation gradients was used for the rest of the experiments.

The rate at which the cells were pumped through the gas exchange fibers affected the subsequent deformability of even fully oxygenated cells. If the flow rate was high (>4 mL/min), the maximum cell deformation was decreased. We surmise that this was likely the result of shear-induced fragmentation occurring as the cells entered or left the fibers. Calculation of Reynolds numbers for flow through the fibers at these rates indicates that turbulence was probably present, increasing the likelihood of cellular fragmentation. The delay time for polymer formation at low HbS concentration and at pH 7.4 was expected to be prolonged, particularly at higher levels of oxygen saturation.²³ Therefore, we wanted to determine the maximum period for which the cells could be equilibrated at 37 °C without undergoing damage and alteration in their deformability properties that could not be explained on the basis of HbS polymer formation. Variation of the equilibration period from 30 to 90 minutes had no significant effect on the DI v pO_2 curve (data not shown). An equilibration period of 30 minutes was chosen for the study.

We performed experiments in which 10-mL aliquots of cell suspension were run through the system while a constant pO_2 was maintained in the gas exchange system (Fig 4). Measurement of the DI at various fixed pO_2 values along the gradient range showed that the DI- pO_2 relationship obtained was very close to the continuous curve obtained using the decreasing oxygen gradient (when the continuous curve was adjusted for the spatial separation of the oxygen electrode and the ektacytometer). Therefore, we conclude that measurements performed using a decreasing gradient from 76 to 0 mm Hg oxygen provide accurate information about the proportion of sickle cells that can deform after equilibration at a given pO_2 value.

Examination of cell morphology at various points along the pO_2 gradient allowed us to define the relationship between the reduction in the DI signal and the percentage of sickle cells in a representative isolated cell population with an MCHC of 32 g/dL at pH 7.2 (Fig 5). We observed both characteristic elongated cells with spicules, and a larger

number of crumpled, or "holly leaf," cell forms, all of which were counted as sickled cells. We note that sickle forms appear in the fixed cell population prior to a point where there is a decrease in the DI signal, and that some discoid cells persist even at very low pO_2 .

Using the conditions defined as described above, we obtained DI v pO_2 curves for 34 samples of density-separated sickle cells from 14 individuals, covering an MCHC range from 27 to 34 g/dL. These curves were characterized by two parameters: the pO_2 at which the deformability loss was first detectable, and the pO_2 at which the DI signal fell to 0.2 (Fig 2). Then the parallel oxygen saturation measurements were used to determine the percent oxygen saturation at these pO_2 values. These data, summarized in Fig 7, show that both the pO_2 and oxygen saturation at which polymer formation interfered with cell deformability rose with increasing MCHC.

To relate the observed deoxygenation-dependent changes in sickle cell deformability to HbS polymer concentration, we used the estimates of Noguchi and her associates for polymer content at a given pO_2 and intracellular HbS concentration.^{7,17} Using data only from samples containing less than 8% HbF, we have plotted the estimated polymer content resulting in the first detectable decrease in cell deformability as a function of MCHC (Fig 8). Since Noguchi's estimates were based on a suspending medium pH of 7.2 and since we were interested in the more physiologic pH of 7.4, we determined the DI as a function of oxygen saturation at both pH 7.2 and 7.4 and made the assumption that equivalent decreases in DI represented equivalent increases in polymer concentration at the two pH values. When the characteristic pO_2 values were thus used to estimate polymer content at which a loss of deformability could first be detected, two observations emerged. First, the minimal detectable polymer increased with increasing MCHC. Second, in the higher MCHC cells it constituted a substantial fraction of the total hemoglobin inside the cells. Thus while it was 5% of total hemoglobin at 27 g/dL, polymer represented 35% at 34 g/dL at pH 7.2.

DISCUSSION

The present study provides new information concerning the rheologic effect of HbS polymer within red cells. While the physiologic interpretation of the results is limited by the fact that the threshold for loss of cell deformability depends on the selected experimental conditions, comparison with the rheologic effect of variations in MCHC and intracellular viscosity¹³ provides some perspective on the problem. The selected conditions for these experiments clearly distinguish oxygenated higher MCHC sickle cells from normal cells in their rheologic behavior, while oxygenated low MCHC cells are not distinct in their behavior. (This essentially repeats our previous observations for fully oxygenated, density-separated sickle cell populations.^{13,24}) Moreover, deoxygenation results in a reduction in the ability of low MCHC sickle cells to deform and in an additional loss in the already reduced deformability of higher MCHC cells. The diffraction pattern generated by the ektacytometer at reduced oxygen tension indicates the presence of a double population

of cells, deforming and nondeforming. Previously, it has been shown that the stably oriented, ellipsoidal pattern characteristic of red cells deforming under laminar shear stress requires a "tank-treading" motion of the membrane around the cell interior.²⁵ Thus, the loss of cell deformability in the ektacytometer can be interpreted as a loss in the ability of the cell to undergo this dynamic, tank-treading motion. This is different from the ability of a cell to undergo gradual deformation from one stationary geometric form to another.

From the data presented in our cell morphology experiment, we have determined that the percent reduction in DI signal for a given percentage of sickle cells is greater than might be predicted from the linear decrease found with glutaraldehyde-fixed normal cells.¹³ There are at least two possible explanations for this result. First, reversibly sickled cells may orient in the shear field of the ektacytometer in a direction perpendicular to that of deforming cells, much like irreversibly sickled cells (ISC). Bessis and Mohandas²⁵ have demonstrated that ISC produce a characteristic horizontal diffraction pattern that results from the perpendicular orientation of these cells to the direction of fluid flow, thus subtracting from the DI signal. A second possibility is that those cells that maintain a discoid appearance may contain sufficient HbS polymer to be partially or totally undeformable. However, recent studies suggest that the latter possibility is unlikely to contribute in a significant way to the interpretation of these data. Nash et al²⁶ and Chien et al²⁷ have noted that alterations in the viscoelastic properties of sickle cells were detected only in those cells that had undergone a morphologic change. Additional kinetic studies by Mozzarelli et al²⁸ were also consistent with these findings. Those authors, using a measurement of the delay time for HbS polymerization to detect preexisting polymer, found that whenever polymer was present, the cells were morphologically sickled.

Taking this into consideration, we suggest that the reduced deformation of sickle cells at low oxygen tension in the ektacytometer reflects the accumulation of an internal mass of polymerized HbS to a size sufficient to interfere with the tank-treading motion of the cell. It should be noted that in deoxygenation experiments such as those conducted here, polymer formation at higher oxygen tensions does not reach equilibrium during the period of experimental observation.²⁸ At these intermediate oxygen tensions, the hemoglobin solution is effectively supersaturated. This probably explains

Fig 7. Relationship between MCHC and critical pO_2 or oxygen saturation values at which loss of cell deformability was first detected (closed circle) and at which the DI fell to a value of 0.2 (open circle). (A) MCHC v pO_2 at pH 7.2. Linear regression analysis gave a correlation coefficient of $r = 0.661$ for initial loss of deformability and $r = 0.669$ for DI equal to 0.2. (B) MCHC v pO_2 at pH 7.4. Linear regression analysis gave a correlation coefficient of $r = 0.635$ for initial loss of deformability and $r = 0.571$ for DI equal to 0.2. (C) MCHC v O_2 saturation at pH 7.2. Linear regression analysis gave a correlation coefficient of $r = 0.663$ for initial loss of deformability and $r = 0.575$ for DI equal to 0.2. (D) MCHC v O_2 saturation at pH 7.4. Linear regression analysis gave a correlation coefficient of $r = 0.812$ for initial loss of deformability and $r = 0.761$ for DI equal to 0.2.

Fig 8. Estimated polymer concentration producing a loss in cell deformability for cells of various MCHC. (A) pH 7.2 (B) pH 7.4. The polymer fraction was estimated using the data from Noguchi¹⁷ as described in Methods.

why the DI signal in our experiments fell sharply over a narrow pO_2 range.

Under the conditions of our studies of low and medium density sickle cells, a decrease in sickle cell deformability could be detected only when the oxygen saturation was reduced to a level at which substantial concentrations of polymer are expected to be formed. This finding is consistent with the recent micropipette studies that demonstrated that enough polymer must form within a cell to cause morphologic change before deformability is impaired.^{26,27} It might have been anticipated that micropipet measurements of membrane deformation at the periphery of the cell would be less sensitive than the ektacytometer to the presence of polymer in the cytoplasm, but such a difference is not apparent in these results. Thus, small amounts of polymer may not interfere greatly either with the tank-treading or viscoelastic deformation of the cells. In addition, our results suggest that the minimum amount of polymer that interferes with cell deformation increases with increasing intracellular

Hb concentration. This could arise because increasing intracellular viscosity obscures the detection of the initial effects of polymer. Alternatively, it may be that HbS polymerization at low HbS concentration results in gradual growth of an extended network of polymer originating from a few nucleation sites, whereas polymerization at high HbS concentrations results in a rapid, multicenter growth of smaller domains of polymer.²⁹ It might be anticipated that the effect of extended polymer structures would be more effective in preventing cell deformation than a larger quantity of small, independent aggregates.

Whatever the reason for the difference in the minimum detectable quantity of polymer in cells of different MCHC, it is of particular interest that the higher MCHC cells appear less sensitive to polymer formation than the low MCHC cells. It has been proposed that the small amounts of polymer that appear to persist in high MCHC cells should have two effects of potential clinical significance.⁹ First, the presence of polymer would eliminate any delay in formation of polymer during brief periods of reduced oxygen tension. Second, the polymer might impair the cells rheologically so that they would be less able to flow rapidly through hazardous areas of low oxygen tension. Although their high intracellular viscosity prevented us from studying this process in very high MCHC cells, our results suggest that small amounts of persistent polymer would have the least rheologic effect on the cells in which it is most likely to be found. Thus, we would anticipate that any deleterious effect of persistent polymer in high MCHC sickle cells at higher pO_2 would be more likely to be exerted through its effect on the rate of polymer formation than on the deformability of cells at high levels of oxygen saturation.

ACKNOWLEDGMENT

We are grateful to Drs Emily Smelzer and Shu Chien for suggestions about the gas exchange system, and to Drs William Lande, William Mentzer, and Stephen Embury for providing blood samples for the study. We are also grateful to Dr Constance Noguchi for providing information on her calculations of HbS polymer content as a function of HbS concentration and oxygen saturation. This is publication No. 76 for the MacMillan-Cargill Hematology Research Laboratory.

Human Neutrophil Degranulation During Extracorporeal Circulation

By Yanina T. Wachtfogel, Umberto Kucich, John Greenplate, Piotr Gluszko, William Abrams, George Weinbaum, Robert K. Wenger, Boguslaw Rucinski, Stefan Niewiarowski, L. Henry Edmunds, Jr, and Robert W. Colman

Cardiopulmonary bypass, especially when prolonged, may result in hemostatic failure and pulmonary dysfunction, which has been attributed to changes in platelets and leukocytes, respectively. It has been well documented that contact of blood with synthetic surfaces causes platelet activation. In this report, we explore mechanisms of the activation of neutrophils during simulated in vitro extracorporeal circulation and document the release of neutrophil lactoferrin and elastase during clinical cardiopulmonary bypass (CCB). Inhibition in the simulated circuit by prostaglandin E_1 (PGE_1) and lidocaine suggests different mechanisms for release of neutrophil-specific proteins. During CCB with a bubble oxygenator it was observed that platelet counts fell to $42\% \pm 2\%$ of baseline. In addition, β -thromboglobulin antigen (β TG), a platelet-specific, α -granule protein marker reflecting the release reaction, increased from 0.15 ± 0.05 to $0.84 \pm 0.11 \mu\text{g/mL}$. Neutrophil counts decreased to $67\% \pm 7\%$ of prebypass levels but then gradually rose as bypass continued. Both lactoferrin, a

neutrophil-specific granule marker, and neutrophil elastase, an azurophilic granule marker, increased in plasma threefold to $1.66 \pm 0.33 \mu\text{g/mL}$ and $1.65 \pm 0.68 \mu\text{g/mL}$, respectively, just before bypass was stopped. When fresh heparinized human blood was recirculated within an extracorporeal membrane oxygenator bypass circuit for 120 minutes, plasma β -TG rose to $5.13 \mu\text{g/mL}$, lactoferrin increased from 0.13 ± 0.04 to $1.62 \pm 0.22 \mu\text{g/mL}$, and neutrophil elastase rose from 0.05 ± 0.02 to $1.86 \pm 0.41 \mu\text{g/mL}$. At 120 minutes, lidocaine ($100 \mu\text{mol/L}$), which inhibits neutrophil activation, delayed release of lactoferrin ($1.33 \pm 0.26 \mu\text{g/mL}$) and markedly inhibited release of elastase ($0.24 \pm 0.05 \mu\text{g/mL}$) but did not inhibit release of β -TG antigen ($5.66 \mu\text{g/mL}$ at 120 minutes). PGE_1 ($0.3 \mu\text{mol/L}$) inhibited significantly the release of β -TG ($0.31 \mu\text{g/mL}$) and elastase ($0.52 \pm 0.11 \mu\text{g/mL}$) and attenuated the release of lactoferrin ($1.57 \pm 0.45 \mu\text{g/mL}$).

DURING CARDIOPULMONARY BYPASS, blood anticoagulated with heparin leaves the normally non-thrombogenic endothelial-lined vascular system and comes in contact with synthetic surfaces of the extracorporeal circuit. Contact with synthetic materials leads to major qualitative and quantitative alterations in platelets that result in released granule contents, prolonged bleeding time, and increased blood loss.¹⁻³ During in vitro recirculation, thrombocytopenia,^{1,2} decreased sensitivity of platelets to aggregating agents,³ decreased α_2 -adrenergic,⁴ and fibrinogen receptors,⁵ secretion of thromboxane B_2 ,⁶ and depletion of α -granule contents³ have been observed.

The release of the lysosomal hydrolase β -glucuronidase during simulated extracorporeal circulation (SECC),⁷ as well as N-acetyl- β -glucosaminidase and β -glucuronidase, during clinical cardiopulmonary bypass (CCB),⁸ suggests neutrophil activation. However, neither of these enzymes are specific for neutrophils and also might be derived from either

platelets⁹ or monocytes.¹⁰ In this study, neutrophil activation was examined in both CCB and SECC by measuring two neutrophil proteins; lactoferrin, a specific granule marker, and human neutrophil elastase (HNE), an azurophilic granule marker.^{11,12} Characterization of the neutrophil response was addressed by observing the inhibitory effect of lidocaine and prostaglandin E_1 (PGE_1) on the release of these proteins in an extracorporeal model.¹

MATERIALS AND METHODS

CCB perfusion circuits contained a centrifugal pump (Biomedicus, Eden Prairie, MN), bubble oxygenator (BOS-102; Bentley Labs, Irvine, CA), and arterial line filter (model 1331) and cardiotomy reservoirs (Extracorporeal, Valley Forge, PA). SECC perfusion circuits (surface area of 0.9 m^2) including a spiral coil membrane oxygenator model 0800-2A (surface area of 0.8 m^2) and a venous reservoir (model R-500-4), were obtained from Sci-Med Life Systems, Minneapolis, and silicone tubing was obtained from Dow Chemical, Midland, MI. Beef lung heparin was obtained from Upjohn, Kalamazoo, MI; PGE_1 and N-formyl-L-Methionine-L-Leucyl-L-Phenylalanine (FMLP) from Sigma Chemical, St Louis; and lidocaine from Elkins-Sinn, Cherry Hill, NJ. Flat-bottomed 96 well polystyrene microtiter plates (Immulon no. 2) were obtained from Dynatech Laboratories, Alexandria, VA. Goat antirabbit IgG (heavy and light chains) covalently coupled to biotin and peroxidase-conjugated avidin as well as peroxidase-conjugated goat antirabbit IgG (heavy and light chains) were obtained from Cappel Laboratories, West Chester, PA.

Purified blood proteins. β -Thromboglobulin antigen (β TG) was purified to homogeneity as previously described.¹³ Purified human lactoferrin and monospecific rabbit antihuman lactoferrin were obtained from Calbiochem-Behring, La Jolla, CA. HNE was purified to homogeneity as described.¹⁴ Antibody raised in rabbits to HNE produced one precipitin arc either by immunodiffusion or immunoelectrophoresis against either purified HNE or a crude neutrophil extract. The HNE immunoassay utilized a 35% ammonium sulfate-enriched IgG fraction that was exhaustively dialyzed.

Clinical cardiopulmonary bypass. In ten patients from whom written informed consent was obtained, lactoferrin and HNE levels

were measured in plasma samples obtained before, during, and after open-heart surgery for valvular or ischemic heart disease. In four of these patients plasma levels of platelet β TG were also sampled at the same time intervals. Blood samples (15 mL) were drawn from a radial artery catheter: (a) before induction of anesthesia; (b) after anesthesia, before heparin; (c) after heparin, before CCB; (d) five minutes after start of CCB; (e) 45 minutes after start of CCB; (f) just before CCB ended; (g) 60 minutes after CCB; and (h) 24 hours after CCB. All patients had CCB with a bubble oxygenator, centrifugal pump, and arterial line filter and were cooled to 26 °C to 28 °C during the procedure. Cold crystalloid potassium cardioplegia was used. Blood aspirated from the operative field was diluted in saline and centrifuged in a Dideco cell sorter (Mironcola, Italy) at 2,800 g and infused into each patient as packed cells.

Blood samples were collected into 1/10 volume sodium citrate (final concentration 0.38%) containing PGE₁ (final concentration 0.3 μ mol/L to prevent in vitro cell activation. Three milliliters were prepared as previously described for β TG measurements.¹³ Twelve milliliters were centrifuged at 2,225 g for 15 minutes at 23 °C. The supernatant was then recentrifuged at 27,500 g for 15 minutes and the resulting supernatant frozen at -70 °C in 0.8-mL aliquots for subsequent measurements of lactoferrin and HNE.

Simulated extracorporeal circulation. Perfusion circuits were assembled from standard silicone rubber components, polycarbonate connectors, and spiral coil membrane oxygenators as described previously.¹ Blood and gas compartments were flushed with 100% carbon dioxide for 15 minutes prior to priming the circuit. Oxygenators were primed by applying a vacuum to the lower gas port. Five hundred milliliters of blood were drawn from random donors who had abstained from any medications for 2 weeks directly into circuit venous reservoirs containing heparin (5.0 U/mL blood), glucose (3.3 mg/mL blood) and, in selected experiments, PGE₁ (0.3 μ mol/L) or lidocaine (100 μ mol/L) (final concentration in whole blood). PGE₁ (10 mg) was first dissolved in 0.01 mL of 95% ethanol and diluted with 0.2% Na₂CO₃ so that the total volume of PGE₁ solution added was 0.05 mL. Blood was permitted to enter the reservoir by gravity without foaming, and any air bubbles were removed from the system before starting the recirculation by a precisely shimmed, barely occlusive pump at a rate of 1.0 L/min for various lengths of time up to 120 minutes. The oxygenators were ventilated with a 95% oxygen-5% carbon dioxide mixture at a rate of 2.4 L/min. Blood temperature was maintained at 37 °C by immersing the reservoir bag in a constant-temperature water bath.

Samples of blood for analysis were collected either directly from the donor or from the reservoir at various times during recirculation. A sample of blood taken from the donor was incubated at 37 °C for 120 minutes and served as a standing control. Plasma samples were prepared as described above.

Blood cell counts. Whole blood platelet counts¹⁵ and leukocyte counts¹⁶ were obtained using a hemocytometer under phase microscopy. A differential leukocyte count was performed to assess the percent of neutrophils in the total population. Hematocrits were measured on each sample, and all counts expressed were corrected for by the calculated hemodilution.

Radioimmunoassay for β TG. Plasma β TG levels were measured as described previously from this laboratory.¹³

Enzyme-linked immunosorbent assay for HNE. Immunochemical measurement of total HNE concentration was performed by an indirect competitive enzyme-linked immunosorbent assay (ELISA) in 96-well microtiter plates as previously described,¹⁷ with the following modifications. Goat antirabbit IgG, conjugated with biotin, was added to each plate and incubated for 60 minutes at 23 °C, the plates were washed, and peroxidase-avidin was added for 30 minutes at 23 °C. The plates were again washed, substrate was

added; plates were incubated for 40 to 60 minutes, and the absorbance was measured at 450 nm.

ELISA for lactoferrin. Plasma lactoferrin levels were measured as described previously from this laboratory.¹⁸

Neutrophil isolation and aggregation. Neutrophils were isolated and aggregation was measured with a platelet aggregometer (Chronolog, Havertown, PA) as described previously from this laboratory.¹⁸ Neutrophils (1×10^7 /mL) were preincubated for 10 minutes at 37 °C with either PGE₁ (0.3 μ mol/L) or lidocaine (100 μ mol/L). They were then challenged with the chemotactic peptide FMLP (100 nM) and extent of aggregation measured. The results were compared to neutrophils that had not been exposed to either drug.

Lidocaine measurements. Plasma levels of lidocaine were measured at 0, 2, 10, 60, and 120 minutes after the start of recirculation, employing an immunoassay lidocaine kit obtained from SYVA, Palo Alto, CA.

Statistical analysis. Student's *t* test (paired) was used to test for significant differences between treatments at the end of SECC at 120 minutes. In all cases $\pm$ values stated indicate the mean $\pm$ the SEM. Analysis of variance was performed using all values for the data on the last three figures. All values listed as significant have a less than 5% occurrence by chance alone.

RESULTS

Clinical cardiopulmonary bypass. Following heparin administration, prebypass platelet counts fell to $92\% \pm 6\%$ of the initial platelet level. By five minutes into bypass, platelet counts had decreased to $40\% \pm 4\%$ (Fig 1) and remained at baseline levels for the duration of bypass. However, plasma β TG rose throughout CCB (Fig 1).

After heparin administration, prebypass neutrophil counts fell to $90\% \pm 4\%$ of the initial level and by 45 minutes neutrophil counts dropped to $67\% \pm 7\%$. However, by 60 minutes postbypass the neutrophil counts had returned to $103\% \pm 6\%$ of the initial neutrophil level (Fig 2). Prebypass

Fig 1. Platelet counts and plasma levels of platelet β TG during CCB. The percent initial platelet count and released β TG was determined: (a) before induction of anesthesia; (b) after anesthesia, before heparin; (c) after heparin, before CCB; (d) five minutes after start of CCB; (e) 45 minutes after start of CCB; (f) just before CCB ended; (g) 60 minutes after CCB; (h) 24 hours after CCB. Each point represents the mean $\pm$ SEM of four patients.

Fig 2. Neutrophil counts, plasma levels of neutrophil lactoferrin, and plasma levels of HNE during CCB. The percent initial neutrophil count, released lactoferrin, and released HNE were determined at the same time intervals as in Fig 1. Each point represents the mean $\pm$ SEM of ten patients.

lactoferrin levels rose from a baseline of $0.06 \pm 0.02 \mu\text{g/mL}$ to $0.56 \pm 0.17 \mu\text{g/mL}$ before bypass. During CCB, lactoferrin levels continued to rise steadily to a maximum of $1.66 \pm 0.33 \mu\text{g/mL}$ just before the end of CCB. However, lactoferrin concentrations fell to $1.45 \pm 0.48 \mu\text{g/mL}$ 60 minutes after bypass and by 24 hours had returned to an initial prebypass level of $0.23 \pm 0.06 \mu\text{g/mL}$ (Fig 2). In contrast, the prebypass levels of HNE did not change. After five minutes of bypass, HNE levels began to increase from a baseline of $0.49 \pm 0.07 \mu\text{g/mL}$. HNE levels rose throughout bypass to $1.65 \pm 0.68 \mu\text{g/mL}$. By 60 minutes, the HNE was still maximal at $1.71 \pm 0.55 \mu\text{g/mL}$ but returned to a value of $0.71 \pm 0.07 \mu\text{g/mL}$ by 24 hours after bypass (Fig 2).

Simulated extracorporeal circulation. During recirculation the circulating platelet count declined within two minutes and slowly increased over the next two hours, as has been reported previously.¹⁹ A steady rise in plasma levels of βTG to $5.13 \mu\text{g/mL}$ at 120 minutes (Fig 3) was observed. Addition of PGE_1 ($0.3 \mu\text{mol/L}$) completely preserved the prebypass platelet counts¹⁹ and prevented βTG release (Fig 3), while lidocaine ($100 \mu\text{mol/L}$) showed no effect on the release of βTG ($5.66 \mu\text{g/mL}$) at 120 minutes (Fig 3).

During SECC, neutrophil counts declined after 30 minutes, but even at 120 minutes the value was $81\% \pm 21\%$ of baseline. Neither PGE_1 ($0.3 \mu\text{mol/L}$) nor lidocaine ($100 \mu\text{mol/L}$) resulted in significant preservation of circulating neutrophil counts (Fig 4).

During SECC there was a steady rise in the plasma levels of lactoferrin from a baseline of $0.13 \pm 0.04 \mu\text{g/mL}$ to $1.62 \pm 0.22 \mu\text{g/mL}$ at 120 minutes. This level of lactoferrin at 120 minutes differed significantly from the level of $0.26 \pm 0.13 \mu\text{g/mL}$ ($P < .05$) found in the control maintained at 37°C

Fig 3. Plasma levels of platelet βTG in recirculated blood during SECC. Released βTG is expressed as μg of βTG per mL of plasma. Values were obtained when heparin anticoagulated blood was recirculated in the presence of PGE_1 ($0.3 \mu\text{mol/L}$) (X-X), lidocaine ($100 \mu\text{mol/L}$) (O-O), or absence of additional drug (●-●). Each point represents the mean of two separate determinations for each drug.

for 120 minutes without exposure to the circuit. PGE_1 ($0.3 \mu\text{mol/L}$) decreased the rate but did not completely inhibit lactoferrin released from neutrophil-specific granules (Fig 5). Lidocaine ($100 \mu\text{mol/L}$) appeared to show an inhibitory effect on the release of lactoferrin for the initial 20 minutes of perfusion (Fig 5). Although the $t_{1/2}$ of PGE_1 is known to be several hours in plasma,²⁰ the $t_{1/2}$ of lidocaine has not been previously examined. To estimate how much lidocaine was present in our circuit, we measured lidocaine levels in our samples and determined the $t_{1/2}$ of its disappearance to be 7 minutes. Since lidocaine was only introduced at the beginning of SECC, lidocaine levels would be 12% of that of the initial concentration at 21 minutes.

During recirculation there was a steady rise in plasma levels of HNE from a baseline of $0.05 \pm 0.02 \mu\text{g/mL}$ to $1.86 \pm 0.41 \mu\text{g/mL}$ at 120 minutes. This level of HNE when analyzed at 120 minutes differed significantly from the level of $0.37 \pm 0.06 \mu\text{g/mL}$ HNE ($P < .05$) found in the 120-minute standing control not exposed to the circuit. In contrast to the effect on either neutrophil count or lactoferrin

Fig 4. Neutrophil counts in recirculated blood during SECC. Neutrophil counts are expressed as percent initial control neutrophil count. The same symbols are used as in Fig 3. Each point represents the mean $\pm$ SEM of seven separate determinations.

Fig 5. Plasma levels of neutrophil lactoferrin in recirculated blood during SECC. Released lactoferrin is expressed as μg of lactoferrin per mL of plasma. The same symbols are used as in Fig 3. Each point represents the mean $\pm$ SEM of seven separate determinations.

release, analysis of variance indicates a significant inhibition of the release of HNE during recirculation by both PGE_1 and lidocaine respectively (Fig 6).

To ascertain whether the inhibition of neutrophil degranulation observed in SECC was due to a direct effect on the cells, neutrophils were preincubated for ten minutes at 37°C with either PGE_1 ($0.3 \mu\text{mol/L}$) or lidocaine ($100 \mu\text{mol/L}$). Both treatments inhibited the maximal extent of in vitro aggregation induced by the chemotactic peptide FMLP by 50% and 53%, respectively (data not shown).

DISCUSSION

Cardiopulmonary bypass is used in approximately 200,000 Americans of all ages each year. The procedure differs substantially from hemodialysis in that the entire cardiac output in CCB passes through multiple components of the perfusion system, whereas in hemodialysis only a small (5% to 10%) portion passes through. The procedure is technically complex and varies in detail from patient to patient. With rare exception the patient's blood is diluted with crystalloid solutions yielding hematocrits of 20 to 25, cooled to 26°C to 28°C , and continuously filtered, washed, centrifuged, and returned to the patient as packed RBCs. In addition, patients receive a wide variety of drugs, anesthetic agents, and occasional blood transfusions. Usually the heart is perfused with cold cardioplegic solution every 20 to 30 minutes, and this solution (typically totalling 1 to 2 L) returns to the perfusate. The extensive dilution and processing of autologous blood and the presence of the patient's metabolic and clearance mechanisms, frustrate attempts to completely define all variables of blood-surface interaction in

Fig 6. Plasma levels of HNE in recirculated blood during SECC. Released HNE is expressed as μg of HNE per mL of plasma. The same symbols are used as in Fig 3. Each point represents the mean $\pm$ SEM of seven separate determinations.

the clinical setting. However, because of possible clinical significance, it is important to verify the appearance and disappearance of various blood elements and cell-specific markers in vivo. Thus, this study for the first time identifies the appearance of lactoferrin and HNE in the circulation of patients who have undergone open-heart surgery.

SECC with fresh heparinized human blood permits qualitative measurements and careful study of the blood elements that directly interact with synthetic surfaces of the cardiopulmonary bypass system. Many of the variables that complicate the interpretation of in vivo results are eliminated. The use of heparin does not pose a problem with regard to neutrophil activation in SECC, since there is no significant rise in plasma levels of lactoferrin and HNE in 120-minute standing control samples that have not been exposed to the circuit. This model has proved particularly valuable in studies of platelet-surface interactions,²¹ and has led to measures to protect platelets during CCB.^{22,23}

CCB activates platelets³ and complement,²⁴ but heretofore activation of neutrophils with concomitant release of neutrophil-specific proteins has not been definitively demonstrated. Several investigators have demonstrated sequestration of neutrophils within capillaries during and immediately after cardiopulmonary bypass.²⁵ Appearance of both of the neutrophil-specific granule protein lactoferrin and azurophilic granule enzyme HNE in the plasma of both CCB and SECC indicates that neutrophils are stimulated and degranulation occurs.

Neutrophils contain many powerful lysosomal hydrolases as well as significant amounts of HNE, a major granular protease.^{11,12} Since the extracellular environment has a neu-

tral pH, released HNE has a potential for catalytic activation and may be important in mediating complications of CCB. HNE is a potent fibrinogenolytic and fibrinolytic enzyme,²⁶ that alters other coagulation proteinases,^{27,28} hydrolyzes platelet glycoprotein 1b,²⁹ reduces the number of thrombin-binding sites per platelet,³⁰ and exposes fibrinogen receptors on the platelet surface.³¹ Thus, HNE present in the extracellular environment after neutrophil degranulation could contribute to the hemorrhagic complications of prolonged CCB. In addition, because HNE attacks lung parenchyma³² and produces endothelial injury,³³ it may play a role in the capillary, pulmonary, and compartmental fluid changes associated with CCB. These changes could occur at HNE concentrations found in this study (Fig 2). When alpha-1-proteinase inhibitor is present, rapid inactivation of HNE occurs,³⁴ but oxidation of the critical Methionine residue of this plasma protease inhibitor may result in its inactivation allowing active HNE to act on connective tissues or other substrates.

Lactoferrin, located in the specific granules, is released at shorter incubation times and/or lower concentration of agonists than HNE.³⁵ It may be more difficult to inhibit lactoferrin exocytosis than HNE release. Lactoferrin may function as an autacoid potentiating other neutrophil agonists.¹²

SECC allows evaluation of agents that may modulate the ability of leukocytes and platelets to extrude their intracellular proteins. Lidocaine (100 $\mu\text{mol/L}$), a known inhibitor of neutrophils⁷ with a $t_{1/2}$ of seven minutes in this system, inhibits the release of lactoferrin for the first 20 minutes of recirculation, and then as the effect of lidocaine begins to wear off, lactoferrin gradually increases to levels seen in the absence of the drug (Fig 5). The concentration of lidocaine that has been used as an antiarrhythmic agent is 5 to 20 $\mu\text{mol/L}$.³⁶ In contrast, lidocaine virtually prevents the appearance of HNE (Fig 6) during SECC since lower concentrations are required for this effect. The effect of lidocaine is probably mediated directly since this compound inhibits neutrophil aggregation *in vitro*. Since we have not yet determined the minimal concentration necessary for inhibition of neutrophil exocytosis, its potential as a chemical inhibitor of neutrophil granule release cannot be ruled out. In contrast, βTG levels are not altered by lidocaine (Fig 3).

PGE_1 (0.3 $\mu\text{mol/L}$), a known inhibitor of platelet function,¹⁹ not only preserves the percent of initial platelet level and inhibits the release of βTG (Fig 3) as observed previously³⁷ but also affects neutrophil degranulation as reflected by the attenuated release of lactoferrin (Fig 5) and total inhibition of HNE degranulation (Fig 6) during SECC. PGE_1 has already been shown to inhibit both leukocyte aggregation in the pulmonary microcirculation³⁸ and granulocyte function.³⁹ We now demonstrate that PGE_1 directly inhibits FMLP-induced neutrophil aggregation, in agreement with the observation of Fantone et al⁴⁰ that PGE_1 decreased the generation of superoxide anion production and lysosomal enzyme secretion of neutrophils in response to FMLP. Additionally, recent work by Holcroft et al⁴¹ describes the ability of PGE_1 to inhibit inflammation in the lungs of patients with adult respiratory distress syndrome.

Although the percent of initial platelet levels during both SECC¹⁹ and CCB (Fig 1) decreases markedly, the percent of initial neutrophil levels falls to a lesser degree in either SECC (Fig 4) or CCB (Fig 2). Platelets adhere to synthetic surfaces of extracorporeal perfusion system^{1,38} and are activated to synthesize thromboxanes⁶ and release α -granule contents.³ Membrane α_2 -adrenergic⁴ and fibrinogen receptors⁵ are reduced, and remaining circulating platelets lose their ability to aggregate in response to established agonists.³ In contrast, the failure of neutrophil counts to decrease to the extent of that of the platelets during recirculation suggests that neutrophil adherence to the synthetic surfaces of the system is less sensitive as an activating mechanism than it is with platelets. Thus, the soluble neutrophil agonists that are generated as a result of activation of other blood elements and/or proteins on the surface of the extracorporeal circuit are implicated in neutrophil activation.

Complement activation occurs during CCB.²⁴ The formation of C5a, a potent neutrophil agonist,⁴² is inferred from observed increases in C3a.⁴³ No direct increase of C5a has as yet been measured, probably because any C5a generated is readily internalized by the neutrophil. Thus, the contribution of C5a as a neutrophil agonist is not yet clear in SECC.

Recent studies by Heller et al⁴⁴ have indicated that during CCB plasma prekallikrein levels significantly decrease, and the generation of kallikrein-like activity has been observed. Plasma kallikrein has been shown to induce neutrophil chemotaxis,⁴⁵ aerobic glycolysis,⁴⁶ aggregation,^{47,48} and degranulation^{17,46} and may serve as a direct agonist in this system. Additionally, kallikrein activates Factor XII to Factor XIIa,^{49,50} which recently has been shown to aggregate and stimulate exocytosis of HNE from neutrophils.¹⁸ Very little is known about the contact system enzymes during CCB, and further investigation is needed.

In this study we have observed increased plasma levels of βTG in both SECC (Fig 3) and CCB (Fig 1). Platelet-specific proteins such as βTG or platelet-derived growth factor may serve as potential neutrophil agonists. Recent studies indicate that other platelet-specific α -granule proteins, platelet Factor 4⁵¹ and platelet-derived growth factor induce neutrophil chemotaxis.⁵² In addition, the formation of leukotrienes, potent autacoids for neutrophils, may also play a role in this activation process. Any or all of the aforementioned neutrophil agonists could singularly or in concert at lower concentrations be responsible for the observed neutrophil activation and subsequent degranulation that we have documented to occur during both SECC and CCB. Identification of the responsible humoral substances would allow for rational and specific intervention during CCB to prevent neutrophil alterations and their potential deleterious consequences during CCB.

Immunogenic Nature of a *Pol* Gene Product of HTLV-III/LAV

By J.S. Allan, J.E. Coligan, T-H. Lee, F. Barin, P.J. Kanki, S. M'Boup, M.F. McLane, J.E. Groopman, and M. Essex

The present studies were initiated to define the coding region of a 34 kilodalton (kd) protein (p34) frequently observed with antibodies from HTLV-III/LAV-infected people by immunoblotting and radioimmunoprecipitation (RIP) techniques. We have directly mapped this viral protein to the *pol* gene of HTLV-III/LAV by radiolabeled amino acid sequence analysis. This region at the 3' end of the *pol* gene is predicted to encode the endonuclease/integrase of the virus. The seroprevalence rate of antibodies to the *pol* gene products p64 and p53 and to the endonuclease p34 were evaluated. Of 161 HTLV-III/LAV seropositive people tested by immunoblotting procedures, greater than 98% had antibodies which reacted to p64/p53 and 92.6%

reacted to p34 indicating that these viral proteins are highly immunogenic in nature. We have also analyzed the serum of nine healthy people living in West Africa who were infected with HTLV-IV, a closely related retrovirus. Nine of nine seropositive people had antibodies that cross-reacted to p34 of HTLV-III/LAV, whereas only seven of nine reacted to p64/p53. These studies and our earlier observations indicate that current diagnostic procedures for screening for HTLV-III/LAV infection may also detect HTLV-IV seropositive individuals, pointing to a need for more specific assay systems.

THE RETROVIRUS responsible for the acquired immune deficiency syndrome (AIDS) termed HTLV-III/LAV or ARV contains an array of potential genes in addition to the classical *gag*, *pol*, and *env* genes of most retroviruses.¹⁻⁴ Since the virus was first isolated much effort has focused on the identification of these viral proteins. Of particular interest has been the observation of variations in serologic profiles of infected people and potential use of these patterns as indicators of disease progression. Previous studies have shown that the *env*-encoded proteins gp160 and gp120 are the most immunogenic proteins irrespective of disease state, whereas the prevalence of antibodies to p24, the major core antigen, decline with disease.^{5,6} As the gene products are identified more information has accumulated as to these serologic variations. Previous studies have identified two proteins, p64 and p53, as encoded by the reverse transcriptase region of the *pol* gene of HTLV-III/LAV.⁷ In addition, indirect evidence has suggested that a 31- to 34-kd protein was encoded by the 3' end of *pol* using bacterially expressed products in a competition immunoblot assay.^{8,9}

Recently a closely related simian retrovirus was isolated from healthy African green monkeys and termed STLV-III.¹⁰ This virus shares many characteristics with HTLV-III/LAV including cell tropism, ultrastructural morphology, and similar protein characteristics. A new human T-lymphotropic virus infecting healthy persons in West Africa shows many of the same characteristics as STLV-III and is indistinguishable serologically.^{11,12} This virus has been named HTLV-IV and immunological cross-reactivity with HTLV-III/LAV has been shown by immunoblotting and radioimmunoprecipitation (RIP) procedures. This has important implications as new diagnostic screening procedures are developed to accurately detect infection by HTLV-III/LAV or a related virus such as HTLV-IV. Here we report the identification of the putative endonuclease/integrase of HTLV-III/LAV, p34, assess the immunogenicity of this viral protein in infected people, and finally show that this protein contains conserved antigenic determinants between HTLV-III/LAV and HTLV-IV.

MATERIALS AND METHODS

The HTLV-IIIB/MOLT-3 cell line was used for antigen preparations (gift from Dr Robert Gallo). Immunoblotting procedures and

methods for virus purification were carried out as previously described.¹¹ Radioimmunoprecipitation and sodium dodecyl sulfate polyacrylamide gel electrophoresis (RIP, SDS-PAGE) were carried out as described.⁵ Cells were radiolabeled with [35-S] cysteine, [35-S] methionine, or [3-H] amino acids in appropriate labeling media for eight hours. The solubilized viral antigens were immunoprecipitated, the precipitates were washed, and resulting protein was electrophoresed on 12.5% SDS gels. Techniques for radiolabeled amino-terminal amino acid sequencing were performed as described.⁶ Radiolabeled viral antigens were immunoprecipitated, separated on SDS gels, electroeluted, dialyzed, and subjected to Edman degradation.

RESULTS

An example of the serum profiles obtained by immunoblotting procedures is shown in Fig 1A. Represented is a healthy laboratory HTLV-III/LAV seronegative person (lane 1), two healthy homosexual seronegatives (lanes 2 and 3), three healthy HTLV-III/LAV seropositives (lanes 4 through 6), three AIDS-related complex (ARC) patients (lanes 7 through 9), and three AIDS patients (lanes 10

Fig 1. Reactivity of antibodies to HTLV-III/LAV specific p34. (A) Western blotting of HTLV-III/LAV antigens. The antigens from SDS-polyacrylamide gels were blotted onto nitrocellulose sheets and test strips reacted with a 1:100 dilution of serum from the following: A laboratory worker (lane 1); healthy homosexual males (lanes 2 through 6); ARC patients (lanes 7 through 9); AIDS patients (lanes 10 through 12); and HTLV-IV-infected healthy West Africans (lanes 13 through 15). (B) Radioimmunoprecipitation (RIP) of [35-S] cysteine- and [35-S] methionine-labeled virus. The antigens were solubilized and immunoprecipitated with the following: A laboratory worker (lane 1), and eight HTLV-III/LAV seropositive individuals (lanes 2 through 9).

through 12). Serum from all seropositive individuals recognize a 34-kd protein (p34). A comparison with RIP/SDS-PAGE is shown in Fig 1B. In every seropositive case shown, a p34 species was observed using this procedure.

To ascertain whether this protein was encoded by the genome of HTLV-III/LAV, radiolabeled sequence analysis was performed. p34 was individually radiolabeled with [3-H] phenylalanine, isoleucine, and lysine, isolated by SDS-PAGE, and subjected to amino-terminal amino acid sequencing. The results are shown in Fig 2. Phenylalanine peaks were observed as positions 1 and 26, lysine peaks were seen at 7 and 14, and an isoleucine peak was seen at position 5 of the p34 sequence. Analysis of the predicted amino acid sequence from the *pol* gene region indicates that p34 maps to the 3' end of this gene and begins at nucleotide sequence 4263 of the HTLV-III/LAV genome as published by Ratner et al.¹ The predicted amino acid sequence is shown in Fig 2B.

The probability of a protein with a random amino acid sequence having lysines, phenylalanines, and an isoleucine in these positions is less than 5.5×10^{-9} .

We analyzed 205 serum samples from people at high risk for infection and those with evidence of HTLV-III/LAV-related disease for the seroprevalence of p34 (Table 1). Of these samples, 161 were positive for antibodies to HTLV-III/LAV proteins by immunoblotting. Overall, 92.6% of seropositives had antibodies to p34, whereas the seroprevalence ratio to p64/p53 was greater than 98%, higher than any other category of protein including the *env*-encoded gp41. It should be noted, however, that all seropositives detected gp120 and gp160 by RIP/SDS-PAGE procedures. Prevalence of antibodies to reverse transcriptase p64/p53 is high irrespective of disease state, but the prevalence to p34 drops slightly in the AIDS category. Additionally, we examined nine representative serum samples from HTLV-IV-

Fig 2. (A) Amino acid sequence analysis of the amino-terminus of p34. The protein was labeled with [3-H] phenylalanine, isoleucine, or lysine and subjected to Edman degradation; radioactivity is shown for each degradation cycle. (B) Alignment of the amino acid sequence of p34 to the predicted amino acid sequence from the 3' end of *pol*. Asterisks represent radiolabeled amino acids and their positions from the amino-terminus of p34. The numbers refer to the amino acid position relative to the first sequence of the *pol* open reading frame.

Table 1. Prevalence of Antibodies to HTLV-III/LAV Viral Proteins by Disease State as Detected by Western Blotting

Category	gp41	p64	p53	p34	p24
Healthy	37(90.2)	41(100)	40(97.5)	39(95.1)	41(100)
ARC	67(100)	67(100)	67(100)	66(98.5)	64(95.5)
AIDS	53(100)	52(98.1)	52(98.1)	44(83.0)	50(94.3)
TOTAL	157(97.5)	160(99.4)	159(98.7)	149(92.6)	155(96.8)

Samples were selected at random from stored sera collected from area hospitals and clinics. Disease states were defined using CDC criteria. The numbers in parentheses reflect percentage positive based on the highest value for a given protein in that disease category. Forty additional samples were tested from healthy and ARC categories and were negative for antibodies to the above proteins. Total number of seropositives was 161 and was used as the denominator for percentage determinations.

infected people for antibodies to the *pol* gene products of HTLV-III/LAV. Three serum profiles are illustrated in Fig 1A, lanes 13 through 15. In addition to reactivity to the *gag*-related antigen p24 of HTLV-III/LAV, all nine samples recognized the p34 protein whereas only seven of nine detected p64.

DISCUSSION

As each new viral protein has been identified and its seroprevalence assessed, a better understanding of the humoral response to infection unfolds. The gene products can then be evaluated on the basis of their relative antigenicity. The present results indicate that the *pol* gene products which include the previously identified p64/p53 and the above-discussed endonuclease p34 are highly immunogenic in

HTLV-III/LAV-infected people. The most immunogenic proteins are the *env*-encoded glycoproteins gp160 and gp120, followed by *pol*-encoded p64/p53, *env*-encoded gp41, *gag*-encoded p24, and *pol*-derived p34. The relationship between serologic profiles and disease state has received much attention from investigators in hopes of finding key serologic markers indicative of clinical progression of disease. Unfortunately, no clear pattern has emerged although relative decreases in seroprevalence of p24, p17, and p34 have been observed in AIDS patients.

Perhaps the most intriguing aspect of the antigenic nature of these viral proteins relates to the high degree of immunologic cross-reactivity between HTLV-III/LAV and HTLV-IV. The significance of these findings is obvious when the design of second-generation screening assays is devised for detecting antibodies to HTLV-III/LAV. As previously reported, many HTLV-IV-infected people test positive by enzyme-linked immunosorbent assay (ELISA) to HTLV-III/LAV.¹¹ The exact nature of this ELISA cross-reactivity is unknown although limited cross-reactivity exists between *env*-encoded proteins for these viruses as well as the *gag*- and *pol*-derived proteins. Detailed analysis of cross-reactive epitopes is necessary, therefore, to devise assays that would include or exclude conserved epitopes. In the former case, inclusion of conserved epitopes would be helpful for screening for HTLV-III/LAV and related viruses in blood banking situations. In the latter case, nonconserved epitopes in an assay system would be preferred for delineating between HTLV-III/LAV and HTLV-IV exposure, which may then have clinical relevance.

A Role for Guanine Ribonucleotides in the Regulation of Myeloid Cell Maturation

By Daniel G. Wright

We have shown previously that induced maturation of the human myeloid leukemia cell line, HL-60, is associated with a selective down-regulation of guanine ribonucleotide synthesis and depletion of intracellular guanosine triphosphate (GTP) and guanosine diphosphate (GDP) pools. We showed, furthermore, that inhibitors of the enzyme, inosine monophosphate (IMP) dehydrogenase, which catalyzes the initial rate-limiting step of guanylate synthesis from the central intermediate IMP, are potent inducers of myeloid maturation in these cells. We now show that induced maturation of HL-60 cells is prevented or impaired if intracellular concentrations of guanine ribonucleotides

are maintained at high levels. HL-60 cells can utilize exogenous guanine and guanosine to maintain GTP and GDP pools through a salvage pathway that bypasses guanylate synthesis from IMP. Moreover, incubation of HL-60 cells with guanosine or guanine (10^{-6} to 10^{-4} mol/L) prevents both the depletion of intracellular guanine ribonucleotides and the induction of myeloid maturation caused by the IMP dehydrogenase inhibitor, tiazofurin. These findings provide strong additional support for the concept that terminal myeloid differentiation is influenced by a guanine ribonucleotide-dependent regulatory system.

© 1987 by Grune & Stratton, Inc.

A NUMBER OF HUMAN myeloid leukemia cell lines have been established which not only can be maintained as immature blast cells in continuous, self-renewing culture but can also be induced to undergo maturation in vitro.¹ These cell lines have attracted considerable interest, for they provide experimentally accessible model systems with which to define basic mechanisms involved in the regulation of myeloid progenitor cell proliferation and differentiation. We used the HL-60 cell line, originally isolated from a patient with promyelocytic leukemia,²⁻⁴ to define a role for intracellular guanine ribonucleotides in the regulation of myeloid cell maturation. As we reported previously, HL-60 maturation induced by *cis*-retinoic acid or dimethylformamide is associated with a depletion of intracellular guanosine triphosphate (GTP) and guanosine diphosphate (GDP), whereas adenylate pools remain relatively intact.⁵ This selective depletion of guanylates occurs in part because guanylate synthesis from the central intermediate, inosine monophosphate (IMP), is down-regulated during induced maturation at the rate-limiting step catalyzed by IMP dehydrogenase (IMPD).⁵⁻⁷ We also observed that specific inhibitors of IMPD [eg tiazofurin (RTC) or mycophenolic acid] are themselves potent inducers of HL-60 maturation.^{5,6} To explore further the apparent relationships between intracellular supplies of guanine ribonucleotides and myeloid maturation, we examined the possibility that induced maturation of HL-60 cells might be prevented or impaired if intracellular concentrations of guanine ribonucleotides are maintained at high levels.

MATERIALS AND METHODS

Maintenance and induced maturation of myeloid leukemia cells. Cryopreserved, early passage HL-60 cells were obtained from the American Type Culture Collection (Rockville, MD). The cells were maintained by passage into fresh serum-free medium⁵ every 3 to 4 days. Cells were studied at maintenance passages 20 through 40. All cell incubations were in 75-cm² tissue culture flasks at 37 °C with 7.5% CO₂ and 100% humidity. Cell counts in culture specimens were determined by hemocytometer chamber counting, and cell viability was assessed by 0.1% trypan blue exclusion.

Cells in log-phase growth (2 to 3 days following media change) were induced to mature by inoculation at 3×10^5 cells/mL into fresh serum-free media supplemented with inducing compounds: 2- β -D-ribofuranosylthiazole-4-carboxamide (RTC or tiazofurin, obtained from the Drug Synthesis and Chemistry Branch, DCT, NCI, National Institutes of Health, Bethesda, MD), 1.0 μ mol/L; retinoic acid (Sigma Chemical, St Louis), 1.0 μ mol/L; or dimethylformamide (Eastman Kodak Co, Rochester, NY), 60 mmol/L. Induced maturation of the cells was assessed by methods described previously for determining NBT reduction^{5,8} and reactivity to the monoclonal antibody OK-M1 (Ortho Diagnostics, Raritan, NJ) as detected with FACS analysis.⁹ For certain studies, cells were exposed to inducing agents in incubation media supplemented with guanosine or guanine (Sigma). Guanosine and guanine were dissolved in sterile dH₂O to prepare stock solutions (10^{-2} mol/L), which were then further diluted in culture media to achieve final concentrations of 10^{-7} to 10^{-4} mol/L. Guanosine was readily soluble, whereas guanine at 10^{-2} mol/L required alkalization with 10 mol/L KOH, 8 μ L/mL dH₂O, to dissolve.

Measurement of intracellular purine ribonucleotide concentrations. Purine ribonucleotide concentrations in perchlorate (PCA) extracts of 2×10^7 cell pellets were analyzed by reverse-phase high-pressure liquid chromatography (HPLC) using an anion-exchange, microparticulate column (Partisil-10 SAX, Whatman, Clifton, NJ) as described previously.⁵ Values for ATP and GTP concentrations (nmoles/ 10^7 cells) were derived from chromatographic peaks detected by ultraviolet (UV) absorbance at 254 nm which were related to standards chromatographed at known concentrations. The use of exogenous hypoxanthine, guanine, and guanosine for synthesis of ribonucleotides was assessed by incubating cells with [8-¹⁴C] hypoxanthine (49.0 mCi/mmol; 1.0 μ Ci/mL), [8-¹⁴C] guanosine (510.4 mCi/mmol; 1.0 μ Ci/mL), or [8-¹⁴C] guanine (55.5 mCi/mmol; 10.0 μ Ci/mL) (New England Nuclear, Boston) followed by PCA extraction of cell pellets and analysis by HPLC with simultaneous measurement of UV absorbance and radioactivity in eluants.⁵ Specific incorporation of radiolabel into ribonucleotides

Table 1. Utilization of Hypoxanthine, Guanine, and Guanosine for the Synthesis of ATP and GTP by HL-60 Cells

Incubation Conditions	¹⁴ C-Hypoxanthine		¹⁴ C-Guanine		¹⁴ C-Guanosine	
	ATP	GTP	ATP	GTP	ATP	GTP
Control						
Nmoles/10 ⁷ cells	51.8	10.9	56.0	13.3	50.7	13.9
Incorporation of radiolabel*	54	70	26	299	33	188
RTC (10 ⁻⁶ mol/L):						
Nmoles/10 ⁷ cells	50.7	4.9	52.4	5.4	47.7	5.1
Incorporation of radiolabel*	47	2	20	992	28	659

HL-60 cells were cultured with or without 2-β-D-ribofuranosylthiazole-4-carboxamide (RTC) for 24 hours in serum-free media as previously described⁶; [8-¹⁴C] hypoxanthine (49.0 mCi/mmol; 0.2 μCi/10⁷ cells), [8-¹⁴C] guanosine (510.4 mCi/mmol; 0.5 μCi/10⁷ cells), or [8-¹⁴C] guanine (1.0 μCi/10⁷ cells; 55.5 mCi/mmol) were added to cell cultures and, after an additional 4 hours, ribonucleotides were extracted from cell pellets with perchlorate and analyzed by high-pressure liquid chromatography (HPLC).⁶ Results are representative of three separate studies; data are means of duplicate measurements, which in all cases varied from the mean by <10%.

*Incorporation of radiolabel = radioactivity (dpm × 10⁻²)/nmole of nucleotide detected in ATP and GTP peaks.

was expressed as radioactivity (dpm × 10⁻²)/nanomole which was calculated by dividing the total dpm (× 10⁻²) detected in a nucleotide peak by the amount of nucleotide (in nmoles) measured in that peak.

RESULTS

HL-60 cells, cultured in a completely defined, serum-free medium, actively salvaged hypoxanthine to generate purine ribonucleotides.⁵ As shown in Table 1, HL-60 cells could also be shown to utilize exogenous guanosine and guanine for ribonucleotide synthesis. Moreover, when these cells were incubated with the IMPD inhibitor tiazofurin (RTC), 10⁻⁶ mol/L, the relative utilization of radiolabeled guanosine or guanine for GTP synthesis was increased, whereas utilization of hypoxanthine for guanylate synthesis, which proceeds through IMP, was almost completely blocked, reflecting IMPD inhibition (Table 1).

As shown in Fig 1, incubation of HL-60 cells with RTC (10⁻⁶ mol/L) resulted in a substantial decrease in intracellular GTP concentrations along with a rise in the ratio of ATP:GTP, reflecting the relatively selective blockade of guanylate synthesis from IMP caused by this agent.^{5,6} However, the addition of guanosine or guanine (10⁻⁶ to 10⁻⁴ mol/L) to the culture medium prevented GTP depletion as well as the increased ATP:GTP ratio caused by RTC under control conditions. Moreover, guanosine and guanine in a similar dose-responsive manner also prevented the induction of myeloid maturation and the decline in cellular proliferation observed in control cell cultures treated with RTC alone (Fig 2). For the studies shown in Fig 2, NADPH oxidase activity, measured as phorbol diester-stimulated NBT reduction, was used as the marker of induced myeloid maturation. Very similar results were obtained, however, when acquisition of the OK-M1 antigen, measured by FACS analysis,⁹ was used to assess induced maturation.

Exogenous guanosine and guanine did not impair the activity of RTC as an IMPD inhibitor. Indeed, the almost complete blockade of hypoxanthine utilization for guanylate synthesis caused by RTC (Table 1) was even more evident when HL-60 cells were incubated with 10⁻⁴ mol/L of guanosine or guanine.

Although IMPD inhibition and guanine ribonucleotide depletion occur rapidly in cells incubated with RTC (within

Fig 1. Reversal of the tiazofurin [2-β-D-ribofuranosylthiazole-4-carboxamide (RTC)]-induced depletion of GTP (A) and increased ratio of ATP:GTP (B) in HL-60 cells when incubation media was supplemented with guanosine or guanine (10⁻⁶ to 10⁻⁴ mol/L). Data are mean values from six replicate studies ± SEM.

Fig 2. Reversal of the tiazofurin [2- β -D-ribofuranosylthiazole-4-carboxamide (RTC)]-induced inhibition of cellular proliferation (A) and myeloid maturation (B) of HL-60 cells when incubation media was supplemented with guanosine or guanine (10^{-6} to 10^{-4} mol/L). Data are mean values from six replicate studies $\pm$ SEM.

6 hours),⁷ the induction of maturation was found to be largely prevented (by >85%) if guanosine (10^{-4} mol/L) was added to the culture medium within 24 hours after incubation of cells with RTC had been started. This effect was progressively diminished if guanosine was added after 24

hours, however, and was inapparent following a delay of 72 hours.

Exogenous guanosine (10^{-4} mol/L) was also found to reverse the depletion of GTP pools in HL-60 cells incubated with retinoic acid (RA) or dimethylformamide (DMF) (Table 2). They also partially reversed the decline in cellular proliferation and the induction of myeloid maturation caused by these agents; however, these effects were not as complete as in HL-60 cells induced with RTC. In contrast to guanosine and guanine, exogenous inosine, adenosine, and hypoxanthine (10^{-4} mol/L) did not reverse the depletion of intracellular GTP or the induction of myeloid maturation observed in HL-60 cells incubated with RTC, RA, or DMF. This result is consistent with a blockade in the synthesis of guanylates from IMP that we have shown to occur in HL-60 cells induced to mature by RTC, RA or DMF.^{5,7} The utilization of inosine, adenosine, and hypoxanthine for guanylate synthesis involves overlapping salvage pathways, each of which ultimately proceeds through IMP, whereas the utilization of guanosine and guanine to form guanine ribonucleotides involves the direct salvage of guanine to GMP, bypassing the synthetic pathway from IMP.

DISCUSSION

Our previously reported observation that IMP dehydrogenase inhibitors are potent inducers of HL-60 cell maturation suggested that a guanine ribonucleotide-dependent system is involved in the regulation of induced myeloid cell maturation, since this enzyme is normally rate-limiting for the production of guanylates in cells. Our present studies, which show that the maturation-inducing effects of selective IMPD inhibition can be completely blocked if intracellular supplies of guanine ribonucleotides are maintained at high levels, provide strong additional support for this idea.

Both exogenous guanosine and guanine were effective in preventing guanine ribonucleotide depletion in cells treated with the IMP dehydrogenase inhibitor, tiazofurin (RTC). Because human cells have been found to lack guanosine kinase activity by which guanosine might be converted directly to GMP, it is presumed that guanosine is first metabolized to guanine by nucleoside phosphorylase and then salvaged directly through a guanine phosphoribosyl transferase-mediated step to form GMP. Thus, both guano-

Table 2. Effects of Exogenous Guanosine and Guanine on HL-60 Cells Exposed to Retinoic Acid and Dimethylformamide

Incubation Conditions	Intracellular (GTP) (nmoles/10 ⁷ Cells)	Cellular Proliferation (Percentage of Increase in Cell Concentration by 4 Days)	Myeloid Maturation (NBT Reduction ΔOD_{515})

RA (10 ⁻⁶ mol/L)	7.0 $\pm$ 0.5	50 $\pm$ 3	196 $\pm$ 12
+ Guanosine (10 ⁻⁴ mol/L)	11.5 $\pm$ 1.5	100 $\pm$ 30	110 $\pm$ 12
+ Guanine (10 ⁻⁴ mol/L)	10.5 $\pm$ 2.0	87 $\pm$ 7	122 $\pm$ 14
DMF (60 mmol/L)	5.2 $\pm$ 0.7	83 $\pm$ 13	107 $\pm$ 17
+ Guanosine (10 ⁻⁴ mol/L)	8.5 $\pm$ 1.5	150 $\pm$ 30	55 $\pm$ 6
+ Guanine (10 ⁻⁴ mol/L)	8.5 $\pm$ 0.8	133 $\pm$ 17	65 $\pm$ 8

HL-60 cells were cultured with and without retinoic acid (RA) or dimethylformamide (DMF), with and without guanosine or guanine for 4 days in serum-free media. Measurements of cellular proliferation represent percentages of increase in cell concentrations during 4-days culture from an initial seeding concentration of 3×10^5 /mL (percentage of increase = absolute increase in cell concentration ($\times 10^5$ /mL) by 4 days/ 3.0×10^5). Measurements of myeloid maturation represent NBT-reduced per 10^6 cells during 30-minute incubation with 100 ng/mL of phorbol myristate acetate.^{6,9} Results are mean values $\pm$ SEM from four replicate studies.

sine and guanine are available as precursors for guanine ribonucleotide synthesis by a final salvage reaction that bypasses the principal synthetic pathways which proceed by IMP. Both guanosine and guanine were examined because of the possibility that they might not be equally accessible for entry into the cells; however, both were similarly effective at comparable concentrations in preventing GTP depletion in induced cells and in preventing induced maturation.

These studies are the first to define a relationship between intracellular guanine ribonucleotide concentrations and cellular maturation in a eukaryotic cell. Such a relationship has been described previously in prokaryotes, however. Guanine nucleotide deprivation induces sporulation of *Bacillus subtilis* and *Sacharomyces cerevisiae* in a manner analogous to the induced maturation of HL-60 cells. Not only do inhibitors of guanylate synthesis (including IMPD inhibitors) trigger the sporulation of these microorganisms, but exogenous guanine, sufficient to protect intracellular guanine ribonucleotide pools, prevents sporulation.^{10,11} The guanine ribonucleotide-dependent system involved in controlling sporulation has not been defined; however, it has been suggested that a GTP-dependent repressor protein may be associated with controlling regions of DNA that directly regulate gene expression relevant to microbial sporulation.¹¹

It is similarly tempting to speculate that guanylate depletion and repletion may influence myeloid maturation in HL-60 cells by affecting the activity of a GTP-binding regulatory protein or proteins. Guanine nucleotide binding proteins are known to regulate a variety of critical cellular

activities, including the ribosomal assembly of polypeptides and receptor mediated responses to extracellular stimuli.¹²⁻¹⁴ The involvement of such GTP-binding proteins in the regulation of hormone-sensitive adenylate cyclase has been particularly well defined,^{13,14} and it is of interest with regard to our current studies that the same experimental maneuvers, which we find to affect both intracellular guanine ribonucleotide concentrations and the induction of myeloid maturation in HL-60 cells, have been shown to affect the activation of adenylate cyclase in intact rat kidney cells by isoproterenol.¹⁵ Hence, it is not unreasonable to suggest that depletion and repletion of intracellular guanine ribonucleotides in HL-60 cells may affect the function of a guanine nucleotide binding protein or proteins involved in regulating the responsiveness of the cells to hormonal signals. Basic mechanisms underlying the neoplastic transformation of HL-60 cells have not yet been defined; however, these mechanisms may involve an autocrine growth hormone or amplified responses by the cells to growth hormones. In either case, IMPD inhibition and guanine ribonucleotide depletion may interfere with the cells' ability to respond to proliferative signals by affecting a "G-protein"-regulated transduction pathway for such signals, thereby triggering cellular maturation as a permissive event.

A Monoclonal Antibody to the Membrane Glycoprotein Complex CD18 Inhibits Polymorphonuclear Leukocyte Accumulation and Plasma Leakage In Vivo

By Karl-E. Arfors, Claes Lundberg, Lennart Lindbom, Kerstin Lundberg, Patrick G. Beatty, and John M. Harlan

Previous *in vitro* findings suggest a critical role for the polymorphonuclear leukocyte (PMN) membrane glycoprotein complex CD18 in PMN adherence and chemotaxis. We examined the effect of the murine monoclonal antibody (MoAb) 60.3, recognizing CD18, on induced PMN accumulation *in vivo*. Rabbits were pretreated with MoAb 60.3, and the chemotactic factors fMLP, leukotriene (LT)_{B₄}, and C5a, as well as histamine, were injected intradermally; 4 hours later, plasma leakage (¹²⁵I-albumin) and the PMN accumulation (myeloperoxidase) were determined. Both PMN accumulation and PMN-dependent plasma leakage were abolished in the inflammatory skin lesions of rabbits

pretreated with MoAb 60.3 as compared with control animals, whereas histamine-induced PMN-independent plasma leakage was unaffected. Intravital microscopy of the rabbit tenuissimus muscle revealed that MoAb 60.3 inhibited both PMN adherence in the venules and migration into the tissue following application of LT_{B₄} and zymosan-activated serum (ZAS). Rolling of PMNs along the venular endothelium was unaffected. Thus, these experiments confirm and extend earlier *in vitro* findings of the critical role of the membrane glycoprotein complex, CD18, in PMN adherence and chemotaxis.

© 1987 by Grune & Stratton, Inc.

THE MEMBRANE glycoprotein complex designated CD18 (LFA-1/Mac-1)¹ is critical for the *in vitro* adherence of stimulated polymorphonuclear leukocytes (PMNs) to endothelial cells.^{2,3} CD18-deficient patients have recurrent infections without pus formation. It has been postulated that the absence of the membrane-associated glycoprotein(s) in these patients prevents adherence of PMNs to the endothelium following activation of the former cell and accounts for the failure of their PMNs to migrate to an inflammatory locus.^{2,3} The CDw18 membrane glycoprotein is recognized by the murine monoclonal antibody (MoAb) 60.3.⁴ Addition of MoAb 60.3 to normal PMNs induces *in vitro* defects in PMN spreading, adherence, and chemotaxis similar to those observed in the patients.⁵

The present study was undertaken to investigate whether MoAb 60.3 also would reduce PMN accumulation *in vivo*, using rabbit inflammatory skin lesions and the rabbit tenuissimus muscle prepared for intravital microscopy. The rabbit was selected for these studies because the antigen recognized by MoAb 60.3 was present in high density on rabbit peripheral blood PMNs when analyzed by FACS and because MoAb 60.3 inhibited stimulated rabbit PMN adherence to cultured endothelial cells (J. Harlan, unpublished observations, 1986).

MATERIALS AND METHODS

Inflammatory skin lesions. Male New Zealand White rabbits, weighing between 1.2 and 1.5 kg, their backs preshaved 12 hours prior to the experiment, were used. The animals were anesthetized with diazepam 5 mg/kg intramuscularly (IM) and thereafter with 10 to 20 mg/kg intravenously (IV) methohexital sodium. The rabbits were either treated with 500 µl/kg of saline IV control (n = 6) or 2 mg/kg of MoAb 60.3 IV (n = 6). Ten minutes later, 10 µCi of ¹²⁵I-labeled human serum albumin was given IV as a plasma tracer, and 100 µL of saline, fMLF (10⁻⁵ mol/L), porcine C5a (2.8 × 10⁻⁷ mol/L and 2.8 × 10⁻⁶ mol/L) and histamine (8 × 10⁻⁴ mol/L) were randomly injected intradermally in duplicate sites in the dorsal region of the animals. Four hours later, the rabbits were reanesthetized, a blood sample was drawn, the rabbits were killed by an overdose of anesthesia, and the skin lesions were carefully removed and dissected free of fat and muscle tissue. After radioactivity measurements of tissue and plasma samples were made, the skin lesions were ground in 0.5% hexadecyltrimethylammonium bromide, freeze-thawed three times, and the myeloperoxidase (MPO) activity was measured in the supernatants. The MPO content of the skin lesions is expressed in units of MPO for each gram of wet weight and albumin extravasation as microliters of plasma exuded for each gram of wet weight.⁶

Intravital microscopy. Direct observation of PMN adherence to the microvascular endothelium was performed using the rabbit tenuissimus muscle prepared for intravital microscopy.^{7,8} The animals were anesthetized with diazepam (5 mg/kg, IM) and thereafter with 20% urethane (1.5 g/kg, IV). LT_{B₄} (final concentration 10⁻⁶ mol/L) and zymosan-activated rabbit serum (ZAS; diluted 1:20) were applied topically to the muscle for a period of 20 minutes. Complement activation following a zymosan concentration of 20 mg/mL of serum, as used here, results in ~3 µg of C5a_{desArg}/mL serum.⁹

Statistics. Wilcoxon signed-rank test was used for calculating *P* values. A *P* value <.05 was considered significant and is denoted in Figs 1 and 2 with an asterisk. Data are given as mean ± SEM.

RESULTS

MPO has previously been shown to be a useful and reliable marker enzyme for PMN accumulation *in vivo*,⁶ and was therefore used to assess PMN accumulation in the inflammatory skin lesions in this study. As shown in Fig 1, in the control animals the chemotactic agents (fMLF, LT_{B₄}, and

Fig 1. PMN accumulation, as measured by myeloperoxidase, in inflammatory skin lesions from the dorsal region of the rabbit. The animals were pretreated with either saline (control) or MoAb 60.3 (2 mg/kg) intravenously 10 minutes prior to the experiment. Values represent mean $\pm$ SEM of six experiments. Asterisks indicate a significant difference as compared with saline-injected skin sites.

C5a) caused a marked local PMN accumulation in the skin lesions as compared with the saline-injected skin lesion. On a molar basis, porcine C5a was found to be a more potent chemotactic agent than both fMLF and LTB₄, although all three agents caused a significant increase in PMN accumulation over saline-injected skin sites in control animals. Moreover, histamine caused a small but significant increase in tissue MPO content. In rabbits pretreated with MoAb 60.3, however, PMN accumulation was completely absent and comparable to the saline lesions as well as intact uninjected skin. Extravasation of PMNs at chemotaxin-injected sites is followed by plasma leakage.¹⁰⁻¹² Plasma leakage in the skin lesions is shown in Fig 2. All the chemotactic agents (fMLF, LTB₄ and C5a), as well as histamine, caused a significant increase in albumin extravasation as compared with the saline-injected site in the control animals. In MoAb 60.3-treated animals, no increase in plasma leakage could be observed for the chemotactic agents, whereas histamine still caused a significant plasma leakage in these rabbits.

In three experiments, the Fc-portion of MoAb 60.3 was removed by pepsin cleavage and the F(ab')₂ portion was used. These fragments inhibited PMN accumulation and PMN-dependent plasma leakage to the same extent as the whole IgG molecule (data not shown).

Direct observation of the tenuissimus muscle after topical application of LTB₄ or ZAS in control animals induced vigorous PMN adherence to the endothelium of the post-capillary venules and subsequent extravasation into the interstitial space. This is shown for ZAS application in Fig 3A and B. In contrast, PMN adherence and extravasation was not observed following LTB₄ or ZAS application in MoAb 60.3-treated rabbits. Figure 3C and D show a post-capillary venule in the tenuissimus muscle of a MoAb

Fig 2. Plasma leakage, as measured by ¹²⁵I-human serum albumin extravasation in inflammatory skin lesions from the dorsal region of the rabbit. The animals were pretreated with either saline (control) or MoAb 60.3 (2 mg/kg) intravenously 10 minutes prior to the experiment. Values represent mean $\pm$ SEM of six experiments. Asterisks indicate a significant difference as compared with saline-injected skin. Shaded area represents normal skin plasma volume.

60.3-treated rabbit before and after ZAS application. Rolling of the leukocytes along the venular endothelium was not reduced by MoAb 60.3, but rather was slightly enhanced in these animals. The striking inhibition of PMN adherence and extravasation by MoAb 60.3 lasted throughout the experiment, ie, for up to 5 hours.

DISCUSSION

We demonstrated that MoAb 60.3 prevents PMN accumulation in vivo, using two different in vivo models in the rabbit; the inhibition of PMN accumulation by MoAb 60.3 is in accordance with, and extends, earlier in vitro findings in which MoAb 60.3 inhibited adherence of stimulated human PMNs to human endothelial cell monolayers.²⁻⁵ Intravital microscopy demonstrated PMN sticking to the postcapillary venular wall, and subsequent extravasation was completely absent in animals pretreated with MoAb 60.3, supporting the results obtained from the inflammatory skin lesions. That rolling of leukocytes along the venular endothelium was not affected by MoAb 60.3 suggests a different adherence mechanism for the rolling and sticking of leukocytes, or, alternatively, the involvement of two different cell populations.

Previous in vitro studies demonstrated that by preventing close approximation of the neutrophil and the endothelial cells, MoAb 60.3 reduced PMN-mediated endothelial injury.¹³ Inhibition of PMN adherence and/or extravasation by MoAb 60.3 also abolished PMN-dependent plasma leak-

Fig 3. The upper left panel (A) shows a postcapillary venule in the rabbit tenuissimus muscle prepared for intravital microscopy (control animal). The lower left panel (B) shows the same venule 1 hour after topical application of zymosan-activated serum (ZAS) with abundant adherent and extravasated PMNs. The upper right panel (C) shows a postcapillary venule in a rabbit pretreated with MoAb 60.3 (2 mg/kg). The lower right panel (D) shows the same venule after a 20-minute topical application of ZAS. In contrast to panel B, no adherent or extravasated PMNs are observed.

age, whereas the PMN-independent plasma leakage was unaffected by MoAb 60.3 treatment.

We conclude, confirming earlier *in vitro* findings, that the membrane glycoprotein complex CD18 is indeed critical for PMN adherence and extravasation *in vivo*. Moreover, MoAb 60.3 reduces PMN-dependent plasma leakage in the inflammatory skin lesions. These findings make MoAb 60.3 a powerful tool in studying the role of PMNs in various

inflammatory events as well as in controlling the inflammatory process.

CONCISE REPORT

The Cellular Basis for Different Fetal Hemoglobin Levels Among Sick Cell Individuals With Two, Three, and Four Alpha-Globin Genes

By G.J. Dover, V.T. Chang, S.H. Boyer, G.R. Serjeant, S. Antonarakis, and D.R. Higgs

Fetal hemoglobin (HbF) levels vary widely among individuals with sickle cell anemia (SS). Previous studies have suggested that HbF levels in SS individuals with alpha-thalassemia (two or three functional alpha-globin genes) are lower than HbF levels in SS individuals with four normal alpha-globin genes. Using immunocytochemical techniques, we studied F cell production as measured by % F reticulocytes, the amount of HbF per F cell, and the preferential survival of F cells versus non-F cells in 51 subjects with four alpha genes, 32 subjects with three alpha genes, and 18 subjects with two alpha genes. Comparison between alpha-globin gene groups was performed for the total sample as well as for a subset of 82 individuals who had replicate samples and a further subset of 39 age-matched individuals. %HbF levels were 6.8, 4.9, and 4.5 percent for the total four-, three-, and two-alpha-globin-gene groups, respectively. The percentage of F

reticulocytes, percentage HbF per F cell, and the enrichment ratio (% F cell/% F reticulocytes) did not change significantly with alpha-globin gene number. Moreover, no correlation existed between alpha-globin gene number and the absolute number of F cells in any group studied. However, there was a strong inverse correlation ($r = -0.407$, $P = .0001$) between non-F cell levels ($1.7 \pm 2.2 \pm 5$, $3.0 \pm 1.0 \times 10^{12}/L$) and decreasing alpha-globin gene number. These data suggest that falling HbF levels among SS individuals with lessened numbers of alpha-globin genes reflect prolonged survival of non-F cells and are not due to intrinsic differences in F cell production or in the amount of HbF per F cell. The improved survival of non-F cells in SS alpha-thalassemia is presumed to be due to the lower MCHC observed in such individuals.

© 1987 by Grune & Stratton, Inc.

ALPHA-thalassemia modifies many hematologic parameters in individuals who have homozygous sickle cell disease (SS). SS individuals with only two alpha-globin genes have higher hemoglobin levels, lower reticulocyte counts, and lower mean corpuscular hemoglobin concentrations (MCHC) than SS individuals with four alpha-globin genes.¹⁻³ In the largest study to date,³ fetal hemoglobin (HbF) levels were lower in SS individuals with two alpha-globin genes than in SS individuals with four alpha-globin genes. The reason for this difference in HbF levels among SS patients has been obscure.

In normal and SS individuals HbF is confined to a subset of erythrocytes called F cells.⁴ HbF levels in patients with SS disease is the summation of three independent variables; first, the number of F cells produced, as estimated by the percentage of F reticulocytes; second, the amount of HbF per F cell; and third, the preferential survival of F cells versus those red cells which contain no detectable HbF (non-F cells).⁵ In a previous study utilizing a small number of SS individuals (10 to 15 subjects per group) we saw no difference in the percent HbF, percentage of F reticulocytes, or the percent HbF per F cell between SS individuals with two or four alpha-globin genes.⁶ Now, in analysis of 101 SS individuals, we substantiate the finding of others³ that HbF levels are lower in SS individuals with two alpha-globin genes than in those with four alpha-globin genes. Furthermore, in this report, we analyze in detail the three cellular variables that determine HbF levels in order to determine the basis for different levels of HbF in these individuals. We conclude that F cell production and the percent of HbF per F cell are the same in SS patients with and without alpha-thalassemia. We find that the difference in HbF levels is directly attributable to the enhanced survival of the non-F cells in SS individuals with coexisting alpha-thalassemia.

MATERIALS AND METHODS

All patients evaluated attended the Medical Research Council Sickle Cell Clinic in Kingston, Jamaica. Eighty-three SS individuals

(51 with four alpha-globin genes, 32 with three alpha-globin genes) were obtained from a previous study of SS siblings randomly selected from the clinic registry.⁷ These patients had not been transfused and had no recent infection or crisis. Alpha-globin gene number was not known at the time of their selection. Eighteen two-alpha-globin gene SS individuals were randomly selected from clinic patients previously identified as having two alpha-globin genes in a survey of the same clinic population.² The average age ($\pm$ SD) for the entire population was 20.6 ± 9.5 years, with no significant age differences between the alpha-globin gene groups. Informed consent was obtained in accordance with the guidelines of both the Johns Hopkins University Medical School Joint Committee of Clinical Investigation and the Clinical Investigation Committee of the University of West Indies.

To ensure reproducibility of hematologic parameters, a second sample was obtained within a one-year interval from most subjects. Eighty-two persons underwent such re-examination. In addition, an age-matched subset was analyzed retrospectively including 13 age-matched individuals from each alpha-globin gene number. Statistical analysis was performed for the total population, for subjects in which second samples had been drawn, and for the age-matched group.

All samples of blood were obtained from venous blood collected in EDTA. Peripheral blood reticulocyte counts were obtained using conventional new methylene blue staining, and red cell indices were performed using an electronic cell counter (Coulter ZBI 6, Coulter Electronics, Hialeah, FL). Alpha-globin gene number was determined or redetermined, in cases of two-alpha-globin gene subjects, by DNA restriction endonuclease analysis utilizing DNA obtained from peripheral blood leukocytes.⁸ Percentage of F reticulocytes was assayed by radial immunoprecipitate reactions.⁹ F cell counts were performed either by the above procedure or by analysis of fixed red cells with a monoclonal anti-HbF antibody.¹⁰ Percentage of HbF levels was determined by alkaline denaturation techniques.¹¹

Statistical distributions were tested for normality by a chi-square test, based on the observed mean and variance. Bartlett's test was used to test for equality of variance. For values that were not normally distributed (% HbF, % reticulocytes), logarithmic transformation was used. The degree of linear correlation between alpha-globin gene numbers and hematologic parameters were assessed by linear correlation coefficient (*r*). Where the distributions were nonnormal, or the variances were unequal, the Spearman-Rank correlation test was used.

RESULTS

Table 1 summarizes the hematologic data for the overall group. No significant correlations were found between alpha-globin gene number and F enrichment ratios, F reticulocytes, or the percentage of HbF per F cell. The remaining hematologic parameters were highly correlated with alpha-globin gene groups: Picograms of HbF per F cell, percentage of F cells, percentage of HbF, MCHC, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and percentage of reticulocytes; all decreased significantly with decreasing alpha-globin gene number. In contrast, hemoglobin levels and red cell number increased with decreasing alpha-globin gene numbers.

Table 2 provides a comparison of the absolute numbers of F cells and non-F cells in SS patients partitioned according to alpha-globin gene number. Although the percentage of F reticulocytes (Table 1) are not correlated with alpha-globin gene number, the absolute numbers of F reticulocytes (Table 2) significantly decrease as the alpha-globin gene number falls. This decrease is due to the significant decrease in the total reticulocyte percentages noted in Table 1. Non-F reticulocyte levels seem to fall with decreasing alpha-globin genes but not significantly so. Although absolute F cell numbers were not correlated with alpha-globin gene numbers, the absolute number of non-F cells per liter was negatively correlated ($r = -0.407$, $P = .0001$) with decreasing alpha-globin gene. The upshot is that alpha-thalassemia is associated with prolonged survival of non-F cells. The outcome is the same when analysis like that in Table 2 is applied to either mean values from 82 subjects who had repeat tests or to 39 age-matched subjects.

DISCUSSION

The intent of this paper was to analyze the origins of differences in HbF levels among individuals with SS disease who have different numbers of alpha-globin genes. Like some previous investigators,^{2,12} we found a significant inverse correlation between the percentages of HbF and the number of alpha-globin genes. In order to determine the origins of these differences, we considered the fact that HbF is discontinuously distributed among red cells in these individuals.⁵ We analyzed the three major variables that contribute to the percentage of HbF levels found in peripheral blood. The first of these, ie, the percentage of F reticulocytes, was not different among the three alpha-globin groups studied (Ta-

†Absolute number of F or non-F cells = (RBC) $\times$ (percentage of F cells or non-F cells).

ble 1). However, the absolute number of F reticulocytes decreased significantly with falling alpha-globin gene number, the level in two-alpha-globin-gene individuals being 77% of that in four-alpha-globin-gene individuals (Table 2). In the absence of significant between-group differences in the percentage of F reticulocytes (Table 1), we presume that the fall in their absolute number is due to a concomitant and significant decrease in overall reticulocyte production (Table 1). These changes would not be expected to have an appreciable effect on HbF levels, since F reticulocytes, in themselves, represent only a few percent of all HbF-bearing cells. While there were significant differences in the second variable affecting HbF production, ie, picograms of HbF per F cell, among the alpha-globin gene categories, there was a parallel fall in the MCH of F cells. Thus no change developed in the actual percentage of HbF per F cell.

The third variable that affects HbF levels is the difference in survival of F cells versus non-F cells in the peripheral blood. This difference in preferential survival was measured two ways. As assessed by comparison of enrichment ratios (% F cells/% F reticulocytes), a decline in enrichment ratios with decreasing alpha-globin gene number (Table 1) was observed. However, the magnitude of this change was not statistically significant. The difficulty with such analysis of enrichment ratios is that it is perturbable by known variation in each of the two estimates, F reticulocytes and F cells, that contribute to it. Consequently, such estimates are less precise than the measure of absolute numbers of non-F cells which utilize only one HbF-centered variable. Here, a highly significant inverse correlation in the number of non-F cells per liter between groups of individuals with decreasing alpha-globin gene number was observed (Table 2). Since non-F reticulocytes did not change between groups, the higher concentration of non-F cells in the two- and three-alpha-globin-gene groups indicate that non-F cells survive

longer in SS individuals with alpha-thalassemia in comparison to SS individuals with four alpha-globin genes.

Why do non-F cells last longer in SS individuals with alpha-thalassemia? We suppose that it is the indirect outcome of a lessened MCHC associated with alpha-thalassemia (Table 1).^{1-3,6} Sick cell hemoglobin (HbS) polymerization is highly dependent upon HbS concentration within the red cell.¹⁴ Recently, Brittenham demonstrated that intracellular HbS polymer levels, calculated on the basis of MCHC and HbS concentration, accounted for at least 80% of the variation in hemoglobin levels among different SS syndromes.¹⁵ Alpha-thalassemia leads to decreased MCHC in all cells⁶ and to a decreased proportion of dense irreversibly sickled cells.^{6,16} The dense cell fraction (MCHC > 37 g/dL) has two hallmarks: it contains very few F cells and exhibits shorter survival than less dense cells.⁶ A decrease in the proportion of dense cells should therefore lead to a relative decrease in the difference between F cell survival and non-F cell survival. The fact is that the majority of non-F cells in SS individuals with two alpha-globin genes have MCHC that are near normal.⁶ Consequently, in this setting, one would expect that non-F cells with near-normal MCHC would last longer than they do when MCHC is elevated. Thus, in these respects, our data indicating prolonged survival of non-F cells in SS individuals with two and three alpha-globin genes are consistent with previous reports.

In summary, differences in HbF levels among SS individuals with different numbers of alpha-globin genes are not due to differences in F cell production or percentage of HbF per F cell. The difference is due to the relatively prolonged survival of non-F cells in alpha-thalassemic SS individuals compared to non-F cells in SS individuals with four alpha genes. We speculate that previously demonstrated declines in MCHC among SS alpha-thalassemic individuals account for this prolonged survival.

Amantadine Potentiates T Lymphocyte Killing by an Anti-Pan-T Cell (CD5) Ricin A-Chain Immunotoxin

By Salvatore Siena, Silvia Villa, Marco Bregni, Gianni Bonnadonna, and A. Massimo Gianni

The studies described in this report demonstrate that 1-adamantanamine hydrochloride (amantadine) is a potent enhancer of the cytotoxic activity of the anti-pan-T lymphocyte (CD5) T101 monoclonal antibody conjugated to purified ricin A-chain (T101-immunotoxin; T101-IT). We also demonstrate that T101-IT in the presence of amantadine does not induce immunotoxin-mediated cytotoxicity in nontarget cells such as human marrow hematopoietic

progenitor cells. These results provide further knowledge for the improvement of ex vivo purification of human bone marrow from normal or leukemic T cells prior to allogeneic or autologous stem cell transplantation, respectively. Furthermore, since amantadine has long been employed safely in human therapy, its use in conjunction with immunotoxins might be exploited in vivo.

© 1987 by Grune & Stratton, Inc.

CELL-specific antibodies coupled to the A-chain subunit of ricin, abrin, or diphtheria toxin give rise to hybrid molecules, referred to as A-chain immunotoxins, that possess specific cytotoxicity against target cells.^{1,2} Unfortunately, A chain immunotoxins do have limitations, particularly in terms of potency and slow kinetics of cytotoxicity. These problems have been partly obviated in vitro by long incubations under conditions nonreproducible in vivo.¹⁻⁸

In a systematic search for substances of potential clinical activity capable of improving A-chain translocation into the cytosol, we tested the symmetrical primary amine amantadine. This drug is selectively concentrated in lysosomes and other acidic organelles,⁹ is capable of elevating endosomal and lysosomal pH,¹⁰ and interferes with receptor recycling¹¹ at the level of compartment of uncoupling receptor and ligand.¹²

We report here that in vitro amantadine, at concentrations nontoxic to human hematopoietic progenitor cells, enhances the activity and accelerates the kinetics of the anti-pan-T cell (CD5) T101 ricin A-chain immunotoxin (T101-IT) against normal T lymphocytes.

MATERIALS AND METHODS

T101 ricin A chain immunotoxin (T101-IT; SR 41322; batch RBM07) consists of the murine monoclonal IgG_{2a} antibody T101 (Hybritech, San Diego, Calif) chemically bound to purified ricin A chain.^{1,5,7} T101 antibody recognizes the 65 kD antigen present on human peripheral blood T lymphocytes (CD5[T, 65 kD] T101).¹³

Normal bone marrow cells were obtained by aspiration from the iliac crests of volunteers, who gave informed consent in accordance with institutional guidelines. Peripheral blood (PB) and bone marrow (BM) mononuclear cells were prepared by density gradient centrifugation over Ficoll-Hypaque (Pharmacia, Piscataway, NJ). Collected cells were washed 3 times with Hanks' buffered saline solution (HBSS) before treatment with T101-IT. Ficoll-Hypaque-isolated mononuclear cells at 10⁷/mL (PB) or 2 × 10⁷/mL (BM) were suspended in HBSS containing amantadine hydrochloride (1-Adamantanamine HCl, Sigma, St. Louis, Mo) and/or ammonium chloride. The incubation medium was adjusted to pH 7.8 by addition of 2 N sodium hydroxide and contained 2% fetal calf serum (FCS) and 10 mmol/L HEPES buffer. After ten minutes at 37 °C, incubation with T101-IT was initiated in ice for ten minutes and then continued at 37 °C. At the end of incubation, cells were washed 4 times at 4 °C with 1% FCS-HBSS and assayed according to the experimental protocol.

To measure lectin-induced polyclonal T cell proliferation, PB mononuclear cells were stimulated with 10 µg/mL phytohemagglutinin (PHA-P, Difco, Detroit, Mich). Mononuclear cells (10⁵ cells/well) were cultured in round-bottomed microtiter plates in 0.2 mL

RPMI 1640 supplemented with 15% FCS, 10 mmol/L HEPES buffer, 100 U/mL penicillin, 100 µg/mL streptomycin, and 2 mmol/L L-glutamine. Triplicate cultures were incubated at 37 °C in a 5% CO₂ humidified atmosphere for 72 hours and then labeled with 1 µCi/well tritiated thymidine (³H-TdR). After eight hours, ³H-TdR incorporation was measured by standard scintillation counting techniques.

To measure lymphocyte proliferative response to allogeneic cells in mixed lymphocyte culture (MLC), responder PB mononuclear cells (5 × 10⁴) were cultured with 5 × 10⁴ irradiated (2,500 rad) stimulator cells (1:1 mixture of allogeneic PB mononuclear cells from two unrelated individuals). Triplicate cultures were performed in supplemented RPMI 1640 with 15% FCS in round-bottomed microtiter plates at 37 °C in a 5% CO₂ humidified atmosphere. After 120 hours, plates were pulsed with ³H-TdR 1 µCi/well. After an additional 24 hours, ³H-TdR incorporation was measured by standard scintillation counting techniques.

The frequency of clonable T lymphocytes in BM samples was evaluated by a limiting dilution microculture assay in PHA-IL 2 feeder cell containing medium according to Kernan et al¹⁴ with minor modifications as previously described.⁸ T lymphocyte frequency was determined by the minimum chi-square method from the Poisson distribution relationship between the cell number seeded per well and the logarithm of the percentage of negative culture wells.¹⁵

The frequency of multipotential (CFU-GEMM), erythroid (BFU-E), and granulomonocytic (CFU-GM) hematopoietic progenitor cells was evaluated by clonal assays as previously described.¹⁶

RESULTS

Unless otherwise specified, 10 nmol/L T101-IT was employed throughout the experiments presented here. In previous studies^{1,7,8} this concentration was found to be optimal in terms of high immunotoxin activity and lack of cytotoxicity to human hematopoietic progenitors.

Viability of PB as well as BM mononuclear cells was assessed by Trypan blue dye exclusion test at the end of four hours incubation. Treatment with 0.1 to 1.5 mmol/L amantadine and T101-IT did not affect cell viability. Higher concentrations, ie, 1.75 and 2 mmol/L amantadine either with or without T101-IT, reduced the number of total viable cells to $84.75\% \pm 13.36\%$ and $27.45\% \pm 9.68\%$ of medium controls, respectively.

In the absence of enhancer molecules, four-hour treatment with T101-IT did not change the mitogenic response of PB T lymphocytes. In contrast, the addition of amantadine to the incubation medium enhanced the activity of T101-IT in a dose-related manner (Fig 1). The most effective nontoxic concentration was 1 mmol/L amantadine which in the presence of 10 nmol/L T101-IT resulted in the inhibition of T lymphocyte mitogenic response to $2.18\% \pm 2.50\%$ of medium controls ($n = 4$). The same amantadine concentration potentiated also the T101-IT inhibition of PB T cell response to allogeneic cells in MLC ($11.72\% \pm 1.26\%$, $12.23\% \pm 1.32\%$, and 12.98 ± 1.40 of medium, amantadine, and T101-IT controls, respectively; $n = 1$).

In parallel experiments, T101-IT in the presence of 10 mmol/L ammonium chloride reduced the PB T cell proliferative response to PHA and to allogeneic cells in MLC to only $41.23\% \pm 21.60\%$ ($n = 3$) and $32.5\% \pm 5.38\%$ ($n = 1$) of controls, respectively. T101-IT in the presence of 20 mmol/L ammonium chloride, or 10 mmol/L methylamine, or 100 μ mol/L chloroquine reduced the T cell proliferative response to PHA to $20.04\% \pm 9.70\%$, $42.30\% \pm 11.30\%$, and $49.00\% \pm 9.83\%$ ($n = 2$) of controls, respectively.

The kinetics of the inhibition of PB T lymphocyte proliferative response to PHA by T101-IT in the presence of 1 mmol/L amantadine or 20 mmol/L ammonium chloride, is shown in Fig 2. Amantadine sped the rate at which T101-IT inhibited T lymphocyte proliferation more dramatically than did ammonium chloride. In addition, the overall enhancement of T101-IT activity was markedly higher with amantadine than with ammonium chloride. A two-hour incubation

Fig 1. Effects of amantadine and/or T101-IT on lymphocyte proliferative response to phytohemagglutinin. Peripheral blood mononuclear cells (10^7 /mL) were treated with 10 nmol/L T101-IT and/or various concentrations of amantadine before culturing in the presence of PHA. Cultures were labeled at 72 hours with ^3H -TdR, and the results are presented as the percentage of thymidine incorporation in treated samples relative to untreated controls. Amantadine potentiates the T101-induced inhibition of mitogenic T cell proliferative response in a dose-related manner.

Fig 2. Effect of T101-IT in the presence of amantadine or ammonium chloride on the rate of T cell mitogenic proliferative response inhibition. Peripheral blood mononuclear cells (10^7 /mL) were treated with 10 nmol/L T101-IT and 1 mmol/L amantadine or 20 mmol/L ammonium chloride. At the times indicated, the cells were washed 4 times at 4°C and then cultured in the presence of PHA. Cultures were labeled at 72 hours with ^3H -TdR, and the results are presented as the percentage of thymidine incorporation in treated samples relative to untreated controls.

with T101-IT and 1 mmol/L amantadine was sufficient to inhibit lymphocyte proliferative response to $1.29\% \pm 0.41\%$ ($n = 2$) of control medium.

To address the possibility that amantadine is toxic to an accessory cell(s) necessary for the *in vitro* T cell activation and proliferation, PB mononuclear cells treated with T101-IT and amantadine were mixed at different ratios with autologous medium-treated PB mononuclear cells and assayed for PHA proliferative response. The observed rate of ^3H -TdR incorporation corresponded to the expected values calculated on the basis of dilution in the cell mixtures, thus ruling out a toxic effect of amantadine plus T101-IT on an accessory cell(s) (data not shown).

Based on the results of the experiments in which PB lymphocytes were the target of the immunotoxin cytotoxicity, human BM mononuclear cells at 20×10^6 /mL were incubated for two hours with T101-IT alone or T101-IT plus either amantadine or ammonium chloride. The frequency of BM T lymphocytes was evaluated by a limiting dilution microculture assay which is the most sensitive method for the detection and enumeration of very low numbers of residual BM T cells.^{14,17}

In the presence of 1 mmol/L amantadine, a two-log depletion of BM T lymphocytes was achieved. In contrast, when 10 mmol/L ammonium chloride was employed instead of amantadine, only one log reduction of BM T lymphocytes was achieved. In all instances, the treatment with T101-IT and/or either enhancer molecule did not significantly alter the recovery of CFU-GEMM, BFU-E, and CFU-GM hematopoietic progenitor cells (Table 1).

DISCUSSION

The data presented in this report demonstrate that amantadine enhances T101-IT cytotoxic effect and that it is

Table 1. Specific Depletion of Human Bone Marrow T Lymphocyte by T101-IT in the Presence of Amantadine or Ammonium Chloride

	Total Nucleated Cells	T Cells	Percentage of Medium-Treated Control		
			Hematopoietic Progenitor Cells		
			CFU-GEMM	BFU-E	CFU-GM
T101-IT	87.1 ± 10.3	101.1 ± 9.8	ND	ND	92.0 ± 7.9
T101-IT plus Amantadine	89.4 ± 8.9	2.20 ± 0.38	72.0 ± 22	69.9 ± 4.1	193.7 ± 75.3
T101-IT plus Ammonium Chloride	91.5 ± 15	13.12 ± 2.10	69.0 ± 19	73.9 ± 15.3	97.1 ± 25.1

Bone marrow mononuclear cells at $20 \times 10^6/\text{mL}$ were incubated for two hours with 10 nmol/L T101-IT in the presence of either 1 mmol/L amantadine or 10 mmol/L ammonium chloride. After 4 washings, cells were assayed for the number of total viable cells, clonable T cells, and hematopoietic progenitor cells. Values shown are the mean $\pm$ SD from two separate experiments. Control CFU-GEMM, $13.6 \pm 3.4/5 \times 10^4$; BFU-E, $336.4 \pm 64.5/5 \times 10^4$; CFU-GM, $88 \pm 51.1/10^5$.

superior to ammonium chloride both in terms of rapidity of action and level of T101-IT cytotoxicity against PB T lymphocytes. In 1984, Casellas et al reported that the degree of enhancement of T101-IT cytotoxicity against T leukemia CEM cells by 1 mmol/L amantadine is inferior to 100 $\mu\text{mol/L}$ chloroquine, 10 mmol/L ammonium chloride, or 10 mmol/L methylamine.⁵ The same authors chose ammonium chloride in their subsequent work.⁷ The present study shows that when targets of T101-IT cytotoxicity are normal T cells, the most effective potentiator is amantadine followed by ammonium chloride, methylamine, and chloroquine. The diversity of our results compared to those of Casellas et al supports the notion that A-chain immunotoxins exhibit variability in target cell toxicity.²

The immediate application of these data is the use of amantadine as optimal potentiator of T101-IT for ex vivo depletion of mature T lymphocytes from bone marrow grafts prior to allogeneic transplantation. Recently, Kernan et al have shown that the number of clonable residual T lymphocytes measured by a limiting dilution assay¹⁴ correlates with the development of GVHD in 32 leukemic patients following transplantation of histocompatible donor T cell-depleted BM. In particular, these authors found that 24 patients who received a median of 3.72×10^4 (0.92 to 16.0×10^4) residual BM T cells per kg of recipient body weight did not develop GVHD. Of the 8 patients who received a median of 23.99×10^4 (18.63 to 43.93×10^4) T cells per kg, 4 had no GVHD, and 4 developed grade I-II (skin only) GVHD.¹⁸ Employing

the same limiting dilution assay for quantitation of residual BM T cells, we show in this report that T101-IT in the presence of amantadine induces a 2 log reduction of BM T lymphocytes without adversely affecting multipotential hematopoietic progenitor cells. Typical untreated BM grafts contain 1.0×10^9 (0.7 to 1.4×10^9) clonable T lymphocytes.¹⁴ Following a 2 log T cell reduction, an average 50 kg patient would receive 2×10^5 (1.4 to 2.8×10^5) T cells per kg. Thus, based on Kernan's studies, data presented here suggest that depletion of BM T cells by T101-IT plus amantadine may be effective in preventing severe grade III-IV GVHD.

Amantadine is a licensed drug employed for prophylaxis of influenza A virus infections in humans.¹⁹ The in vitro concentrations found to be active in present experiments cannot be achieved in the blood of patients treated with amantadine.²⁰ For this reason we are now investigating whether amantadine analogues will prove active at clinically occurring concentrations. T101-IT in the presence of non-toxic amantadine concentrations prompts its immediate use for a more efficient ex vivo depletion of human bone marrow T lymphocytes.

ACKNOWLEDGMENT

We are grateful to Groupe Sanofy, Centre de Recherches Clin Midy, Montpellier, France, for supplying T101-IT. We are also indebted to Dr Nancy A. Kernan for helpful discussions.

Possible Absence of Common Polymorphisms in Coagulation Factor IX Gene in Japanese Subjects

By Tetsuhito Kojima, Mitsune Tanimoto, Tadashi Kamiya, Yuichi Obata, Toshitada Takahashi, Ryuzo Ohno, Kotoku Kurachi, and Hidehiko Saito

Four distinct intragenic polymorphisms in the coagulation factor IX gene which have been reported to be important for family diagnosis of Caucasian hemophilia B were studied in 51 normal Japanese subjects (21 males and 30 females). High-molecular-weight DNA prepared from peripheral blood lymphocytes were digested with endonuclease, Ddel, MspI, TaqI or XmnI, and were studied by Southern blot analysis with factor IX complementary DNA

as a probe. None of the minor fragments produced by these enzymes was found in the normal Japanese DNA samples tested, although the probe detects minor allelic forms in control Caucasian DNA samples. Our data suggest that the frequent polymorphic sites found in Caucasians are possibly absent in the Japanese population.

©1987 by Grune & Stratton, Inc.

COAGULATION factor IX (Christmas factor) is a vitamin K-dependent plasma protein that participates in the early phase of blood clotting. The absence or functional deficiency of this protein causes a severe bleeding tendency known as hemophilia B or Christmas disease. The recent isolation of a complementary DNA (cDNA) sequence coding for this protein¹⁻³ and the gene for factor IX^{4,5} has opened a new era in the genetic study of hemophilia B. The disease results from heterogeneous genetic causes including single amino acid substitutions,⁶ partial gene deletions,^{7,8} and intronic point mutations.⁹ Besides the structural analysis of abnormal genes, the discovery of restriction fragment length polymorphisms (RFLPs) within the factor IX gene¹⁰⁻¹⁴ has facilitated the clinical application of these polymorphic fragments as genetic markers for family diagnosis such as carrier detection and possible prenatal diagnosis.

Hemophilia B is one of the most common hereditary coagulation disorders in the Japanese population. The occurrence of the disease among Japanese is almost equal to that in whites.¹⁵ We have recently initiated the study of RFLPs in Japanese hemophilia B patients and their families. Interestingly, the majority of normal Japanese subjects was found to possess only the major RFLP fragments of the factor IX gene. Our results suggest that there may be another type of limitation of molecular genetic techniques in family diagnosis of hemophilia B, in addition to the limitations already pointed out by Graham et al.¹⁶

MATERIALS AND METHODS

Twenty milliliters of peripheral blood was drawn from 51 normal Japanese subjects (21 males and 30 females) and 5 normal white subjects (2 males and 3 females) after informed consent. High-molecular-weight DNA was prepared from peripheral blood lymphocytes by sodium dodecyl sulfate (SDS)-proteinase K method followed by phenolchloroform extraction as described elsewhere.¹⁷

Ten to twenty micrograms aliquots of DNA were digested with endonuclease Ddel, MspI, TaqI, or XmnI (Boehringer Mannheim, Indianapolis). DNA fragments were electrophoresed on 0.6% to 1.5% agarose gels and transferred onto nitrocellulose filters (Schleicher & Schuell, Inc, Keene, NH) by Southern's method.¹⁸ Hybridization was carried out with ³²P-labeled factor IX cDNA probe, pHFIX (1.45kb PstI fragment)¹ for 16 hours at 65 °C. The filters were washed and subjected to autoradiography with Kodak XAR-5 film (Eastman Kodak, Rochester, NY).

Fig 1. The location of factor IX intragenic common RFLP sites analyzed in this study. TaqI and XmnI sites that produce minor allelic forms are indicated with solid arrows (▼). Insertion polymorphism region detected by Ddel is shown with an open arrow (Δ).

RESULTS

Factor IX gene RFLPs analyzed in this study are shown in Fig 1. Genomic DNA samples from 51 normal Japanese subjects (21 males and 30 females) were digested with TaqI endonuclease and then analyzed with factor IX cDNA probes. While control genomic DNA from two white subjects showed the TaqI minor allelic form (1.3kb fragment), no minor fragment in 20 Japanese genomic DNA samples was detected under the same experimental conditions (Fig 2A).

Fig 2. Southern blot analysis of high molecular-weight DNA from normal Japanese and Caucasian subjects with factor IX cDNA probe. Four restriction endonucleases, TaqI (A), MspI (B), XmnI (C), and DdeI (D) were used for digestion of DNA. Factor IX cDNA probe detects 1.3kb TaqI minor fragment in two of three control Caucasian (c) DNA samples (10 to 20 μ g DNA per lane) tested. 5.8kb MspI, 6.5kb/5.0kb XmnI, and 1.74kb DdeI minor forms are observed in Caucasian DNA samples. Minor allelic forms are, however, not observed in any Japanese DNA samples tested. Agarose gel electrophoresis was performed at 1.0% to 0.7% (TaqI), 0.6% (MspI), 0.7% (XmnI), and 1.5% (DdeI).

Similarly, both the 5.8kb MspI and 6.5kb/5.0kb XmnI minor alleles were observed among the white control samples (Figs 2B and C). All the Japanese DNA samples in the same blot, however, possessed neither the MspI nor XmnI minor fragment polymorphism. DdeI digestion was also carried out, but no 1.74 kb minor allele was found among the normal Japanese subjects analyzed (Fig 2D).

The incidence of these four enzyme-derived minor alleles in 81 Japanese X chromosomes was compared with that in white X chromosomes previously described in the literature^{10,12,13} (Table 1). The results indicated that the Japanese factor IX gene is significantly different from the white factor IX gene in terms of the four enzyme polymorphisms analyzed ($P < 0.01$).

DISCUSSION

We demonstrated that the previously described intragenic RFLPs in the factor IX gene produced by endonuclease DdeI, MspI, TaqI, and XmnI are not found in 51 normal Japanese subjects. While DdeI polymorphism is produced by a 50 base pair insert in intron A, the other three RFLPs are generated by point mutations (Fig 1). The experimental conditions employed in this study permitted detection of minor alleles in Caucasian DNA samples digested with each restriction enzyme (Fig 2). To avoid the geographical influences of normal Japanese DNA samples, unrelated random blood donors were chosen for this study, from 10 different prefectures situated in two of four major islands in Japan. The data obtained in this study clearly indicated that common factor IX gene RFLPs among Caucasians are possibly absent in Japanese. Similar results have also been

Table 1. Frequency of Intragenic Polymorphisms in Factor IX Gene in Japanese and Caucasian Subjects

Enzymes	Japanese	Caucasian	P Value
TaqI (1.3kb)	0 n* = 81	0.29 n = 77	$P < 0.01$
MspI (5.8kb)	0 n = 81	0.20 n = 46	$P < 0.01$
XmnI (6.5kb/5.0kb)	0 n = 81	0.29 n = 72	$P < 0.01$
DdeI (1.74kb)	0 n = 81	0.24 n = 74	$P < 0.01$

The incidence of minor alleles in the factor IX gene in Japanese subjects was compared with that in Caucasians. The data for Caucasians were collected from the literature (ref 10 for TaqI, ref 13 for MspI, ref 12 for XmnI, and ref 12 for DdeI). Statistical analysis was done by Fisher's exact test.

*Number of X chromosomes analyzed.

obtained in the Asian population including Japanese, Chinese, and Filipinos in Seattle (Chen S-H, Kurachi K: unpublished observation).

Recent isolation of the factor IX cDNA sequence and successful cloning of the factor IX gene has brought a new era in the clinical diagnosis of hemophilia B. After discovery of the informative TaqI RFLP, which is located in intron D,¹¹ several other RFLPs have been found. These polymorphisms have already been used for clinical diagnosis for Caucasian hemophilia B families.¹²⁻¹⁴ There are, however, several limitations in molecular genetic diagnosis for hemophiliacs as pointed out recently.¹⁶ The results described here suggested that there is one more type of limitation for diagnosis of hemophilia B in certain races, such as the Japanese.

CONCISE REPORT

Effect of Human Recombinant Granulocyte Colony-Stimulating Factor on Hematopoietic Injury in Mice Induced by 5-Fluorouracil

By Michiya Shimamura, Yukio Kobayashi, Akira Yuo, Akio Urabe, Tetsuro Okabe, Yoshinori Komatsu, Seiga Itoh, and Fumimaro Takaku

Intravenous (IV) administration of 5-fluorouracil (5-FU) caused severe hematopoietic injury in mice. Daily administration of purified human recombinant granulocyte colony-stimulating factor (rG-CSF) accelerated recovery from neutropenia in these injured mice. Granulocyte-macrophage progenitors (CFU-GM) in spleen were markedly increased

by rG-CSF, while rG-CSF was less effective on the regeneration of CFU-GM in femoral marrow. The accelerated recovery from neutropenia in the mice might be mainly due to the stimulation of granulopoiesis in spleen by rG-CSF.

© 1987 by Grune & Stratton, Inc.

IT IS WELL KNOWN that the proliferation and differentiation of hematopoietic progenitors are directly regulated by the stimulating factors specific to each lineage of the progenitors,¹ respectively. Recently the genes encoding some human hematopoietic factors, such as erythropoietin,² granulocyte colony-stimulating factor (G-CSF),³ and granulocyte-macrophage colony-stimulating factor (GM-CSF),⁴ have been cloned. Our laboratories have also succeeded in producing human recombinant G-CSF (rG-CSF) independently.⁵ In vivo activities of the preparations of rG-CSF have been already demonstrated.^{5,6} In consideration of clinical applications of rG-CSF, we have been trying to estimate the therapeutic effect of rG-CSF on an animal model of neutropenia induced by anti-cancer drugs. In this paper we report an enhancing effect of rG-CSF on the granulopoietic recovery in mice injured hematopoietically by 5-fluorouracil (5-FU).

MATERIALS AND METHODS

Human G-CSF was purified to homogeneity from a protein-free culture cell line, Balanche-1,⁷ and the amino-terminal sequence of G-CSF was determined by a gas-phase sequencer (unpublished results). Using poly (a)⁺RNA prepared from human macrophages, a cDNA library was constructed by the methods of Okayama and Berg.⁸ The resulting cDNA library was screened by the synthetic oligonucleotide probes, which were predicted by the amino-terminal sequence. The amino acid sequence deduced from the cloned cDNA was identical to that reported by Souza et al.³ The cDNA was expressed in *Escherichia coli* K12 MM294 by construction of an expression plasmid for G-CSF using pGEL-1 containing the *trp* promoter,⁹ and the mature protein was purified to homogeneity as previously reported.¹⁰ Details on cloning and expression of the cloned cDNA will be described elsewhere (unpublished results). Units of rG-CSF activity were defined according to the method of Nicola et al.,¹¹ ie, the rG-CSF concentration required for half-maximal stimulation of colony formation by 75,000 BDF₁ mouse (Charles River, Japan) bone marrow cells in a semisolid culture medium was defined as 50 U of activity. As a measurement of purity, the purified rG-CSF was analyzed by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis according to the method of Laemmli¹² and was tested for endotoxin contaminations using a limulus amoebocyte lysate assay.³ The purified rG-CSF was dissolved in endotoxin-free normal saline for subcutaneous (SC) injection to mice in doses of 5×10^4 to 2×10^5 U/mouse/day.

Female BDF₁ mice (7 weeks old) were injected intravenously (IV) with 5-FU (200 mg/kg body weight; Sigma Chemical, St Louis) on day 0. Daily SC administration of rG-CSF was carried out from day 0. The 5-FU-treated control mice received only saline. In one experiment mice were sampled randomly from each group on days 5

Fig 1. Analysis of human G-CSF and rG-CSF on an SDS-15% polyacrylamide gel stained with silver. (A) 2 µg of rG-CSF; (B) 2 µg of G-CSF from Balanche-1 cells; (C) molecular weight markers.
